REPORT PREPARED FOR Norwegian Environment Agency Postboks 5672 Sluppen, 7485 Trondheim	CONTRACT REF. Contract number 17078061	
ABSTRACT This report presents results from the monitoring of atmospheric composition and deposition of air pollution in 2019, and focuses on main components in air and precipitation, particulate and gaseous phase of inorganic constituents, particulate carbonaceous matter, ground level ozone and particulate matter. In 2019, it was an unusual wide-spread episode during April causing high concentrations of most pollutants at several sites.		
NORWEGIAN TITLE Overvåking av langtransportert forurensset luft og nedbør. Atmosfæriske tilførsler 2019.		
KEYWORDS Atmosphere and climate/ Atmosfære og klima/ Aerosols and particles/ Aerosoler og partikler Ground level ozone/ Bakkenært ozon Acid rain and eutrophication/ Sur nedbør og overgjødsling		
ABSTRACT (in Norwegian) Denne rapporten omhandler resultater fra overvåkningsprogrammet for langtransportert forurensset luft og nedbør og atmosfæriske tilførsler i 2019. Rapporten presenterer målinger av uorganiske hovedkomponentene i luft og nedbør, partikulært karbonholdig materiale, partikkelsmasse og bakkenært ozon. I 2019 ble det observert en uvanlig omfattende episode med høye koncentrasjoner av luftforurensning på flere stasjoner.

Sammendrag

Overvåkingsprogrammet for langtransporterte luftforurensninger, som presenteres i denne rapporten, omhandler målinger av svovel- og nitrogenforbindelser i luft og nedbør, elementært og organisk karbon (EC/OC) i partikler, bakkenært ozon, partikkelfmasse (PM_{10} og $PM_{2.5}$) og størrelsesfordeling av partikkellantall på 16 norske bakgrunnsstasjoner. I tillegg rapporteres målinger av levoglukosan på Birkenes. For første gang rapporteres nivåer av OC og EC for den arktiske stasjonen Zeppelin på Svalbard.

Hovedmålet er å kvantifisere nivåene og dokumentere eventuelle endringer i atmosfærisk tilførsel, noe som er viktig for å kunne evaluere luftforurensningenes effekt på økosystem, helse, materialer og klima. Programmet startet i 1973 med målinger av svovel- og nitrogenforbindelser og ble senere utvidet med bakkenært ozon (1985), partikler og EC/OC (2000/1) og størrelsesfordeling av partikkellantall (2010).

Kjemisk sammensetning og geografisk fordeling

Birkenes i Agder observerer vanligvis de høyeste nivåene av luftforurensning på grunn av nærhet til utslippsområdene på kontinentet. Noen stasjoner i innlandet påvirkes av regional landbruksaktivitet som kan gi relativt høyt ammoniumnivå. De høyeste nivåene av EC, OC og NO_2 observeres på Hurdal i Akershus, sannsynligvis på grunn av at denne regionen er relativt tett befolket, og har relativt mye veitrafikk. Målestasjon i Finnmark opplever hvert år høye nivåer av sulfat på grunn av påvirkning fra nærliggende smelteverk på Kola-halvøya i Russland. Den høyeste våtvæsningen av svovel og nitrogen skjer langs kysten fra Agder til Hordaland.

Organisk materiale utgjorde den største fraksjonen av PM_{10} ved alle stasjonene (34 – 46%), fulgt av sekundære organiske forbindelser (SIA) (17 – 29%) og sjøsaltpartikler (6 – 21%), mens mineralstøv ble estimert å utgjøre 13% av PM_{10} på Birkenes. Både konsentrasjonen og det relative bidraget av SIA og sjøsaltpartikler til PM_{10} var betydelig høyere ved Birkenes-observatoriet enn for de to andre stasjonene, hvilket reflekterer områdets nærhet til henholdsvis store antropogene utslippsområder på det europeiske kontinentet og til havet.

Episoder

Hvert år observeres det episoder med langtransportert luftforurensning forårsaket av meteorologi, som fremmer langtransport, kombinert med høye utslipper. I 2019 var det en spesielt langvarig hendelse gjennom april. April 2019 var den andre-varmeste og nest-tørreste april i Norge siden 1900, forårsaket av et vedvarende høytrykksystem i Europa med varm og tørr luft over en lengre periode. Episoden inneholdt forurensning fra omfattende branner i Øst-Europa, støv sannsynligvis fra Sahara, samt forurensning fra trafikk og industri på det kontinentale Europa. Episoden i april førte til høye ozon-nivåer på mange steder, spesielt på Tustervatn i Nordland, hvor det ble observert det nest høyeste ozon-nivået siden oppstarten av overvåkningen i 1989. Stasjonene som måler karbonholdige partikler opplevde også usedvanlige høye nivåer i denne aprilepisoden. Forhøyede levoglukosan-nivåer målt på Birkenes, kombinert med transportmodellering og satellittbilder, peker på jordbruksbranner i Øst-Europa. Analyse av sporelementer viser også et betydelig bidrag av mineralstøv.

Overskridelser

Årsmiddelkonsentrasjonene av PM₁₀ og PM_{2,5} lå langt under nasjonale og internasjonale grenseverdier (EU) og retningslinjer (WHO) for luftkvalitet på alle målestasjonene. Heller ikke døgnmiddelverdier (PM₁₀) overskred grenseverdier og retningslinjer.

EUs grenseverdi («target value») for ozon knyttet til beskyttelse av vegetasjon og helse har ikke blitt overskredet på mange år i Norge. EUs langtidsmål for ozon («long-term objective») knyttet til helse ble derimot brutt på alle stasjoner unntatt Zeppelinfjellet, og langtidsmålet for beskyttelse av landbruksvekster ble overskredet på en stasjon (Birkenes) i 2019. UN-ECEs grenseverdi for skog ble overskredet på fire stasjoner i 2019. WHOs retningslinjer for luftkvalitet for ozon, og de nasjonale retningslinjene satt av Folkehelseinstituttet, overskrides i varierende grad hvert eneste år i Norge. EUs grenseverdi for informasjon til publikum ble ikke overskredet i 2019 og har heller ikke blitt brutt på mange år i Norge.

Trender

Konsentrasjonene av nitrogen- og svovelkomponenter i luft og nedbør i 2019 var noe lavere enn nivået i 2018, mens i et lengre perspektiv er det tydelig nedgang i nivåene. Årsmiddelkonsentrasjonene av PM₁₀ og PM_{2,5}, samt OC og EC i 2019 var innenfor ett standardavvik av langtidsmidlet. En oversikt over alle trendene er vist i tabell 1. Trendene gjenspeiler i stor grad utslippsreduksjonene som har skjedd på det europeiske kontinentet de siste tiårene, men årlige variasjoner i meteorologi kan skjule noe av effekten av utslippsreduksjonene, spesielt for ozon.

Summary

The atmospheric monitoring programme, presented in this report, includes observations of sulfur- and nitrogen compounds in air and precipitation, elemental- and organic carbon (EC/OC) in aerosols, ground level ozone, particulate matter (PM_{10} and $PM_{2.5}$) and aerosol size distribution, at a total of 16 sites in the Norwegian rural background environment. In addition, observations of levoglucosan at the Birkenes Observatory are reported. OC- and EC-measurements for the Arctic site Zeppelin are reported for the first time.

The main objective is to quantify the levels of these pollutants and to document any changes in atmospheric pollution, which is important for studies on its influence on ecosystems, human health, materials and climate change. The programme started in 1973 with measurements of sulfur and nitrogen compounds and was later extended with ozone (1985), aerosol particles, carbonaceous aerosol (2000/1), and aerosol size distribution (2010).

Chemical composition and geographical distribution

Birkenes in Agder commonly observe the highest levels of air pollution due to its proximity to the emission regions at the continent. Some inland sites are influenced by regional agricultural activities and experience relatively high ammonium levels. The highest EC-, OC- and NO_2 -levels are seen in Hurdal in Akershus, likely due to influence from the more densely populated region surrounding this site, including road traffic. The site in Finnmark experience high levels of sulfate due to influence from the nearby smelters at the Kola Peninsula in Russia. The highest wet deposition of inorganic ions occurred along the coast from Agder to Hordaland.

Organic matter was the major fraction of PM_{10} at all sites (34 – 46%), followed by secondary inorganic aerosol (SIA) (17 – 29%) and sea salt aerosol (6 – 21%), whereas a 13% contribution of mineral dust was estimated at the Birkenes Observatory. The SIA and sea salt aerosol contribution was substantially higher at the southernmost site Birkenes due to the proximity to major anthropogenic emission regions in continental Europe and to the sea, respectively.

Episodes

Every year there are episodes of air pollution caused by meteorology, favouring long range transport of air masses, combined with high emissions. In 2019, there was a special large-scale event during April, which caused high concentrations of many pollutants at several of the mainland sites. April 2019 was the second warmest and second driest April in Norway since 1900 caused by a persistent high-pressure system in Europe with warm and dry air for a long period. The episode carried pollution from extensive fires in Eastern Europe, including Ukraine and western Russia, as well as dust from probably Sahara, as well as pollution from transport and industry in continental Europe. This April-episode caused elevated ozone levels at several sites, particularly at Tustervatn in Nordland, experiencing the second highest ozone level since the start of the monitoring in 1989. The sites measuring carbonaceous aerosol also experienced atypically high levels during this period. Elevated levoglucosan-concentrations observed at Birkenes, combined with Flexpart transport modelling and satellite images, point to agricultural fires in Eastern Europe. Trace element analysis show a substantial influence of mineral dust as well.

Exceedances

PM_{10} - and $PM_{2.5}$ -observations were all well below the EU limit-values, the national limit-values and the WHO and the National Air Quality Guidelines on an annual as well as on a 24-hour basis.

EU's ozone target values for protection of human health and vegetation have not been exceeded for many years in Norway. EU's long-term objective for protection of human health was, however, violated at all the stations except at the Zeppelin Mountain in 2019. WHO's air quality guideline for ozone as well as the national guidelines are exceeded every year in Norway at a varying extent. EU's information threshold to the public was not exceeded in 2019 and has not been broken for many years in Norway. EU's long-term objective for protection of vegetation was exceeded at one station (Birkenes) in 2019. UN-ECE's critical level for forests was exceeded at four stations in 2019.

Trends

The concentration levels of nitrogen- and sulfur compounds in air and precipitation were in 2019 somewhat lower than in 2018, and the long term trends are substantially declining. The annual mean concentration of PM₁₀, PM_{2.5}, OC and EC were all within one standard deviation of the long-term mean. An overview of the long-term trends are shown in Table 1.1. The trends reflect to a large extent the emission reductions which have taken place in the European continent the last decades, although inter-annual variations in meteorology could mask the effect of the emission reductions, particularly for ozone.

Table 1.1: Trends in annual levels using Mann-Kendall test and Sen slope estimates. Note that trends are given for sites with significant change only.

Component	Sites	1980-2019	1990- 2019	2000-2019

Monitoring of long-range transported air pollutants in Norway

Annual Report 2019

1 The monitoring programme 2019

The atmospheric monitoring programme presented in this report focuses on particulate and gaseous phase inorganic constituents, particulate carbonaceous matter, ground level ozone and particulate matter in the Norwegian rural background environment. The main objective is to quantify the levels of these pollutants and to document any changes in the atmospheric long-range transported pollution. An important goal is to measure the effectiveness of the protocols, i.e. the 1999 Gothenburg Protocol to Abate Acidification, Eutrophication and Ground-level Ozone (UN/ECE, 1999)

The monitoring sites are located in areas where the influence of local sources are minimal, and thus the sites being representative for a wider region. Regular sampling of precipitation on a daily basis in Southern Norway dates back to 1973. After that, the measurement programme and the monitoring network was expanded to provide improved information on atmospheric contribution of air pollution for all of Norway.

After the conclusion of the SNSF (*"acid rain's effects on forest and fish"*) project in 1979, a national monitoring programme organized by the Norwegian Environment Agency was initiated in 1980. Several changes in the content of the measurement programme, as well as in the number and distribution of monitoring sites, has taken place during the 40 years life-time of this monitoring programme, although only small changes since 2011. The measurements presented in the current report are part of different national projects and programmes:

- *The National monitoring programme on behalf of The Norwegian Environment Agency:*
 - Ozone at four sites (Birkenes, Tustervatn, Kårvatn, Zeppelin)
 - Daily measurements of NO₂ at four sites (Birkenes, Hurdal, Tustervatn, Kårvatn)
 - Weekly measurements of particulate matter (PM₁₀ and PM_{2.5}) and EC/OC at three sites (Birkenes, Hurdal, Kårvatn)
 - High time-resolution measurements of particle number and size distribution at Birkenes
 - Daily measurements of particulate and gaseous inorganic compounds in air and precipitation at two sites (Birkenes and Zeppelin; weekly for precipitation at Ny-Ålesund)
 - Meteorology at three sites (Birkenes, Zeppelin and Hurdal)
 - Inorganic ions in precipitation at Svanvik (part of the programme for ICP Material)
- *Measurement programme to preserve long-time data series on behalf of the Ministry of Climate and Environment, co-financed by NILUs internal monitoring programme taken in 2019 taken over by the Norwegian Environment Agency in 2019 :*
 - Daily measurements of particulate and gaseous inorganic compounds in air and precipitation at three sites (Hurdal, Kårvatn and Tustervatn)
 - Weekly measurements of main inorganic ions in precipitation at seven sites (Vikedal, Treungen, Brekkebygda, Høylandet, Nausta, Vatnedalen, Løken).
 - Ozone at three sites (Hurdal, Sandve and Prestebakke)
 - Levoglucosan at Birkenes
- *Norway-Russia programme on behalf of The Norwegian Environment Agency:*
 - Weekly measurements of main inorganic ions in air and precipitation at Karbukt

- *Local air pollution programme, co-financed by the municipalities in Porsgrunn, Skien and Bamble:*
 - Ozone at Haukenes
- *Funding from the Ministry of Climate and Environment to support the monitoring activities at the Zeppelin Observatory*
 - EC/OC, levoglucosan and other organic tracers at Zeppelin

Data and results from the national monitoring programme of air pollutants are also included in various international regional programmes. Five of the sites are part of EMEP (European Monitoring and Evaluation Programme) under the CLRTAP (Convention on Long-range Transboundary Air Pollution, <http://www.unece.org/env/lrtap>). Data from several of the sites are also being reported to CAMP (Comprehensive Atmospheric Monitoring Programme) under OSPAR (the Convention for the Protection of the marine Environment of the North-East Atlantic, <http://www.ospar.org>); AMAP (Arctic Monitoring and Assessment <http://www.apmap.no>) and WMO/GAW (The World Meteorological Organization, Global Atmosphere Watch programme, <http://www.wmo.int>). A subset of the data are also reported to EEA (European Environmental Agency, <http://www.eea.europa.eu/>) as required in the EU air quality directive (EU, 2008). Near real time data of ozone is reported continuously to both Norwegian (<http://www.luftkvalitet.info>) and European (EEA) air quality warning services). All the data are openly available at <http://ebas.nilu.no>.

The present report is one of four reports, which cover the national monitoring of atmospheric composition in the Norwegian rural background environment. The other three reports are published separately, of which the first focuses on persistent organic pollutants and heavy metals (Nizzetto et al., 2020), the second covers the monitoring of the ozone layer and UV (Svendby et al. 2019), whereas the third is on climate gases and aerosol particles influence on climate (Myhre et al., 2019). The site locations and key information on the monitoring programme at the actual sites are illustrated in Figure 1.1. Detailed station information, monitoring programme and measurement frequencies are provided in Annex 2, whereas sampling methods and chemical analysis are described in Annex 3.

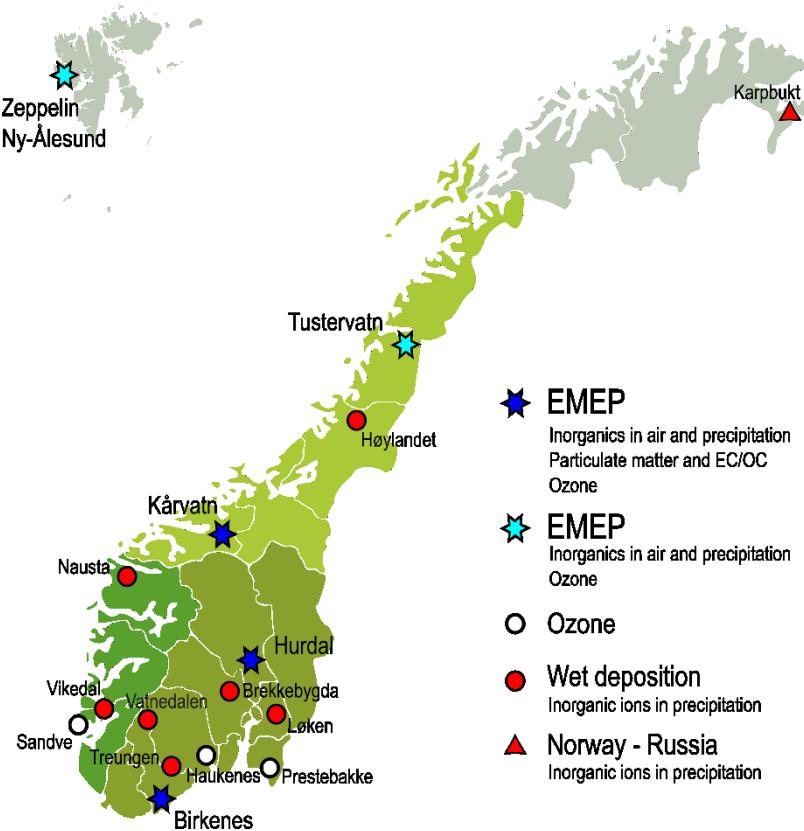

Figure 1.1: Norwegian background sites and their measurement programme 2019. Details are found in Annex 2. The colour codes indicate the different regions/zones used in EU's Ambient Air Quality Directive (2008).

2 The weather in Norway 2019

The variation in meteorological conditions from year to year is decisive for the observed concentrations of pollutants in air and precipitation in Norway. At rural sites, the level of pollutants is mostly determined by atmospheric transport from other countries. The distribution of high- and low-pressure systems controls this transport and temperature, humidity and precipitation are determining the degree of deposition, washout and chemical transformation in the air masses. Knowledge of the meteorological conditions and how it varies from day to day and from south to north is therefore important for understanding the air pollutant levels.

In 2019, the annual average temperature for the country as a whole was 1.2°C above the normal (all normals refer to the 1961-1990 period), while the average precipitation was 15 % higher than the normal (Met. Institute, 2020). This makes 2019 the 20th warmest year and the 15th wettest year since 1900. Except for a few sites in Troms and Finnmark, the average temperature exceeded the normal in the entire country. The highest temperature anomalies were observed at Spitsbergen with an annual average temperature around 3°C above the normal. At the meteorological station at Svalbard airport the monthly mean temperatures have been above the normal every single month since December 2010.

January - March was characterised by temperatures above the normal and much higher precipitation than normal in most of the country. Frequent low-pressure systems coming in from the west lead to strong winds and precipitation particularly in western and northern Norway. The mean temperature in the Arctic was around 5°C above the normal in January. In February the mean temperature at the mainland of Norway was 3.5°C above the normal, implying that it was among the 15-20 warmest February months since 1900. Temperature records were broken at several sites this month, peaking at Landvik near Grimstad with 18.7 °C on 26 February. Some sites in Nordland and Troms received three times the normal precipitation in February. March was also warmer and wetter than normal. The mean precipitation for the country as a whole was 160 % of the normal, which implies that it was among the 10 wettest March months since 1900. Some areas in SE Norway received three times the normal precipitation this month.

Following the three months of mild and wet conditions, April was an exceptionally warm and dry month. For the country as a whole, this was the second warmest and the second driest April since 1900 with a mean temperature 3.3°C above the normal and with only 40 % of the mean precipitation. Temperature records were broken at several sites, and the temperature anomaly was particularly high in Finnmark and at the west coast with mean temperatures 4-5°C above the normal. The month was dominated by southerly and south-easterly winds, and during 20-27 April an episode with high levels of surface ozone and particles was observed in certain areas. This episode is discussed in more detail in the report.

By the end of April, the weather situation changed completely, and strong northerly winds with polar air masses lead to low temperatures in the entire country. Later in May, SE Norway was influenced by several low-pressure systems causing heavy rainfall. The country as a whole received 175 % of the normal precipitation, making this month the 4th wettest May since 1900. At many sites on the western coast, May was colder than April. The wet conditions continued in June in many areas particularly in southeast and North Norway, which received more than twice the normal precipitation. Some areas in the south experienced episodes with sudden extreme rain events.

By the first part of July, the weather gradually became drier and warmer, and a heatwave influenced many parts of the country later that month. A peak temperature of 35°C was observed in Nordland (Mosjøen) in this period. The month as a whole was warmer and drier than normal. By August more variable weather conditions were observed with more precipitation than normal on the west coast,

but some areas in North Norway experienced only 50 % of the normal precipitation. The dominating mild and wet conditions continued in most of the country in September. A peak temperature of 28°C was observed as late as 21 September in Buskerud.

October brought a marked change in the weather with cold and dry conditions. The mean temperature was 1.4°C below the normal and the precipitation 70 % of the normal, but areas in the south-east received more precipitation than normal, up to twice the average. These conditions continued in November when record-dry conditions were seen in the western part, whereas the southeast received 2-2.5 times the normal precipitation caused by frequent low-pressure passages in the southeast.

December was very mild and wet with a mean temperature 3.4°C above the normal and 140% of the normal precipitation, which means it was among the 20th warmest and the 10th wettest December months since 1900. This was linked to frequent low-pressure systems both in the southern and northern parts.

3 Inorganic components

3.1 Observations in 2019

3.1.1 *Chemical composition in precipitation*

All sulfate values given in the present report are adjusted for the contribution of sulfate associated with sea salt. The sea-salt sulfate content is calculated based on the ratio of sodium, or magnesium and chloride, to sulfate in seawater, and is according to the procedures suggested by EMEP (EMEP/CCC, 2014). From 2013, measurements of precipitation on a daily basis, as recommended by EMEP and WMO/GAW, is conducted at the four EMEP sites on the Norwegian main land, the other sites with weekly sampling.

Monthly and annual concentrations and wet depositions for all sites are listed in Annex A.1.1-A.1.19, and all years in A.1.21, while Table 3.1 lists the annual mean concentrations and depositions at all stations for 2019.

Regional distribution of mean concentrations and wet depositions are shown in Figure 3.1 and Figure 3.2. Table 3.1, Figure 3.1 and Figure 3.2 show that the ion content decreases along a South to North transect excluding the county of Finnmark. The highest concentrations of sulfate, nitrate and ammonium are seen in south and southeast while the wet depositions are highest in southwest, correlated to the high precipitation amount on the west coast. The site in Finnmark are influenced by emissions from Russia and the content of sulfate is particularly high (Berglen et al., 2019)

Table 3.1 shows that all regions, except the most continental parts of southern Norway and Finnmark, observed significant amounts of sea salts. At most sites, there was an excess of cations, which probably is due to the content of bicarbonate or other anions of weak acids that are not determined. At Vatnedalen it also seems to be a problem with the sea salt ions of unclear reason.

As seen for previous years, the highest annual mean concentrations for the major components were generally observed at the Birkenes site (Table 3.1); the exceptions were observed for sulfate, which were higher for Karpbukt due to the influence of emissions from Nikel (Russia). Being situated only 20 km from the Skagerrak coastline, Birkenes is the site in Norway being the most influenced by long-range transport from the European Continent and UK, hence this finding is to be expected. However, some inland sites are influence by regional agricultural activities and experience somewhat higher ammonium concentrations, i.e. Løken. The highest wet deposition loads of sulfate, nitrogen components and strong acid occurred along the coast from Aust-Agder to Hordaland.

Table 3.1: Annual volume weighted mean concentrations and total wet deposition of inorganic ions at Norwegian background stations, 2019.

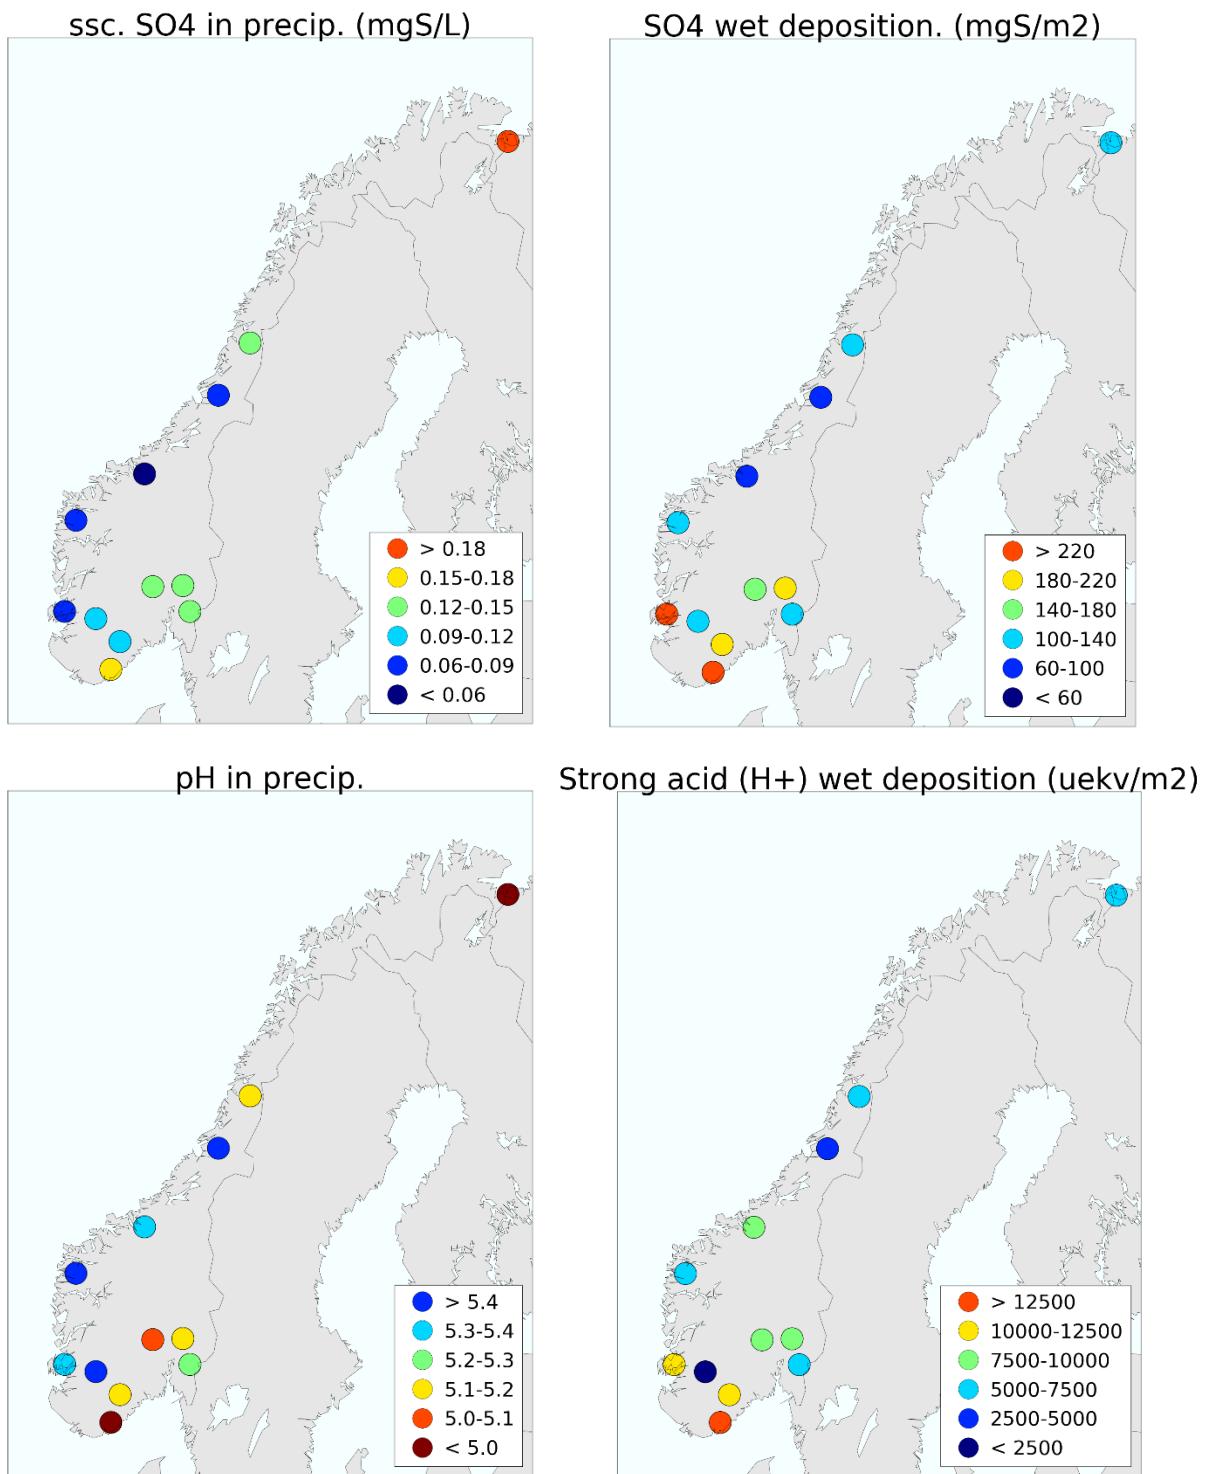

Figure 3.1: Annual volume weighted mean concentrations and total wet deposition of sulfate (sea salt corrected) and strong acid (pH), 2019. Note that the colours only resemble the spatial distribution and do not indicate any exceedances of limit values or similar

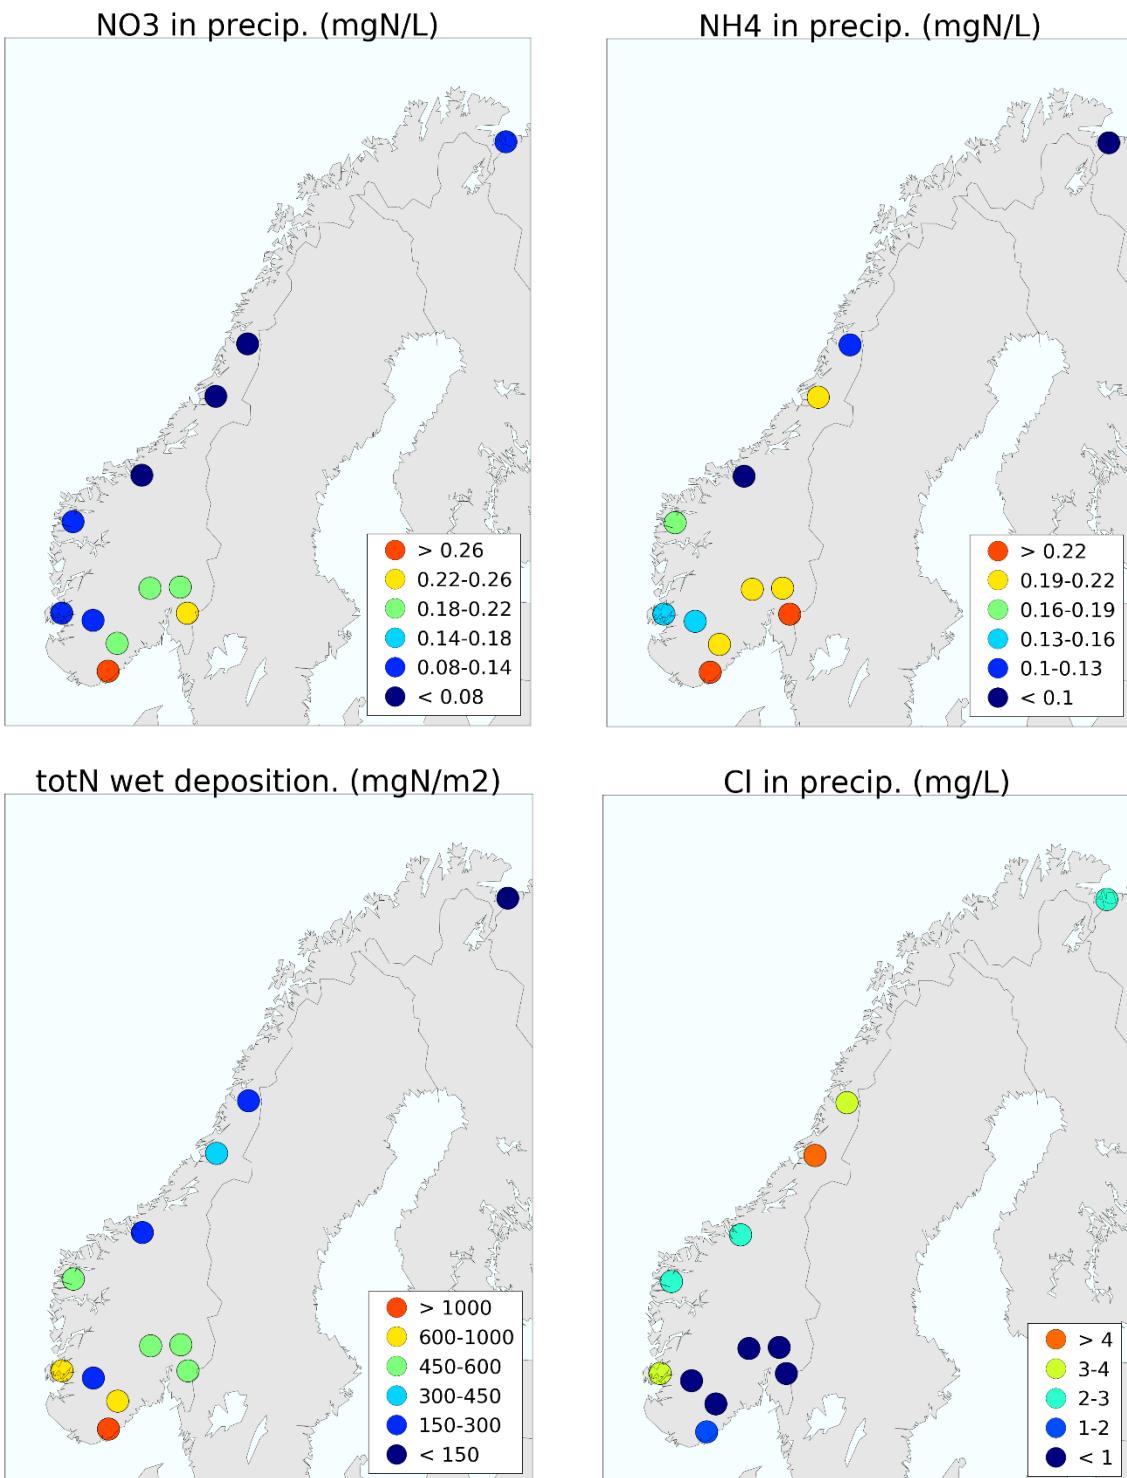

Figure 3.2: Annual volume weighted mean concentrations of nitrate, ammonium, chloride and total wet deposition of nitrogen (nitrate + ammonium), 2019. Note that the colours only resemble the spatial distribution and do not indicate any exceedances of limit values or similar.

Figure 3.3 shows monthly volume weighted mean concentrations and wet deposition of sulfate, nitrate and ammonium in different parts of Norway, 2019. All the monthly data are given in the tables in Annex 1. There are quite large variabilities in the concentrations as well as depositions throughout the year, though it is not a general pattern common for all regions and components.

In 2019, the highest concentrations were for most ions seen in April. For wet deposition the highest levels were seen in May to August, but there are large variations between regions and periods. The measured wet deposition of sulfate, shows that between 32% and 56% of the annual total deposition arrives during the ten days with highest deposition at the four sites with daily measurements during the whole year (Table A1.20).

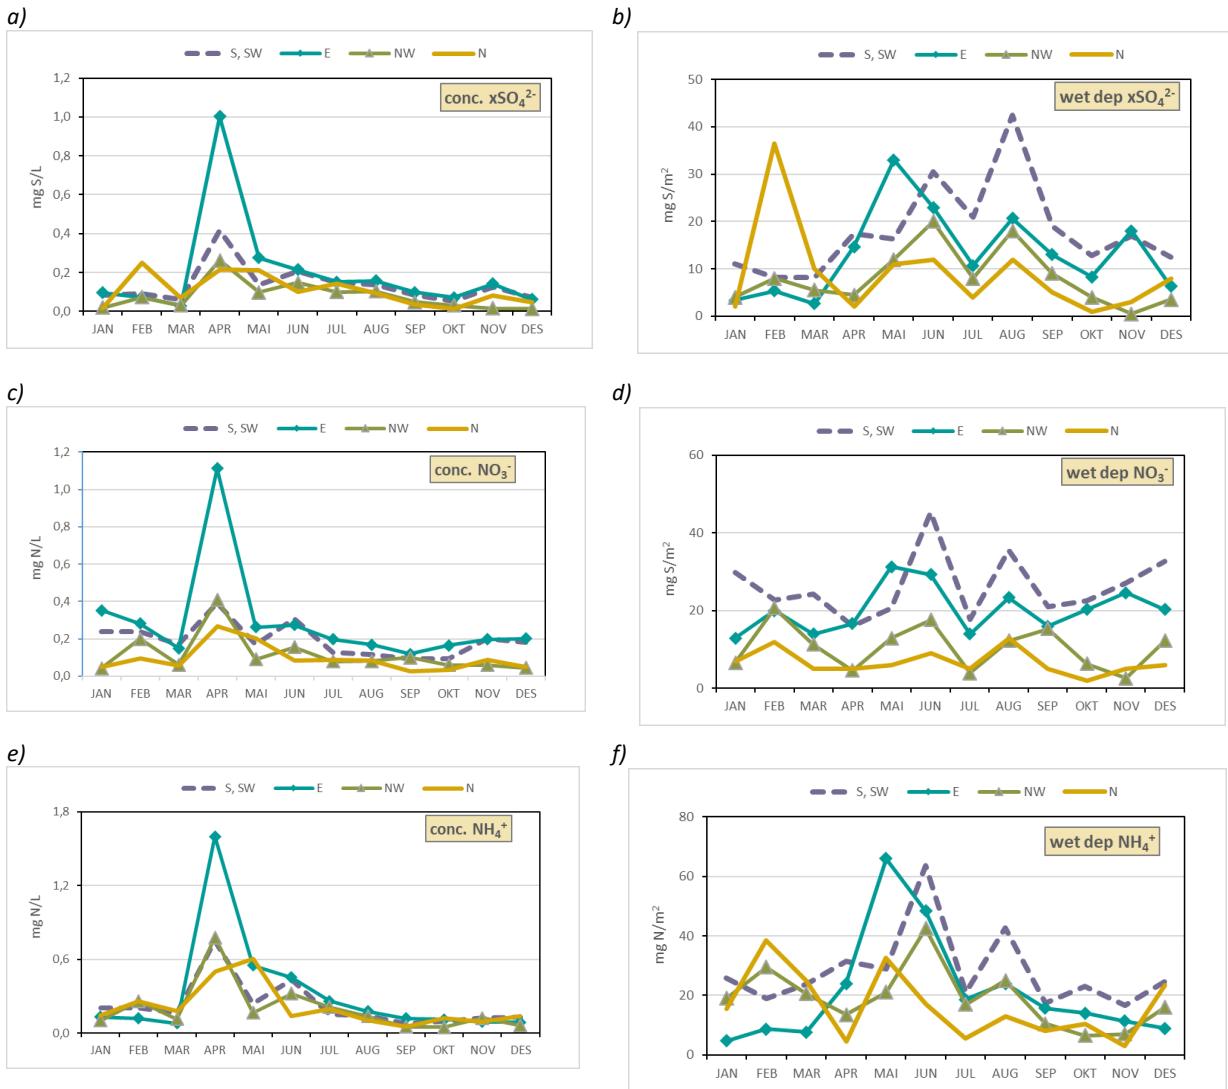

Figure 3.3: Monthly volume weighted mean concentrations (left: a,c,e)) and wet deposition (right: b,d,f)) of sea salt corrected sulfate (top) nitrate (middle), ammonium (bottom) in different parts of Norway, 2019, S, SW: South and South west is the average of the sites Birkenes, Vatnedalen, Treungen and Vikedal; E: East (Løken, Hurdal, Brekkebygda); NW: Northwest (Nausta and Kårvatn); N: North (Høylandet and Tustervatn).

3.1.2 Chemical composition in air

Daily measurements of inorganic components in air was carried out at five sites in 2019, And all of these are EMEP sites (Figure 1.1). Table 3.2 shows the annual mean concentrations while the monthly data are given in A.1.22-A.1.33. The monthly means of the sulfur and nitrogen components are illustrated in Figure 3.4. The maximum and percentile concentrations of SO_2 , SO_4^{2-} , sum of ($\text{NO}_3^- + \text{HNO}_3$), NH_4^+ and sum of ($\text{NH}_3 + \text{NH}_4^+$) are given in Table 3.3 to Table 3.8.

Table 3.2: Annual mean concentrations of inorganic components in air at Norwegian background stations, 2019.

Annual mean concentrations of sulfur dioxide in air are quite low at all the sites, in 2019 the highest, though quite low mean concentration was observed at the Zeppelin Observatory with 0.07 µg S/m³. The highest daily average was observed at Zeppelin and Tustervatn with 1.2 µg S/m³ on 15 January and 25 April. At Zeppelin this episode was cause but air masses arriving from Russia (Siberia) while at Tustervatn it was long rang transport of air pollution from continental Europe . This latter episode was also seen at Hurdal and Kårvatn, both for SO₂ and SO₄²⁻ and several other components. The episode in April is described in more details in Chapter 7.

The highest annual mean particulate sulfate level was measured at Birkenes (0.20 µg S/m³), while the highest episodes were observed Tustervatn and Kårvatn and Hurdal due to the above mentioned episode. Highest NO₂ levels were observed in Hurdal with an annual mean of 0.5 µg N/m³. This station is influenced by the relatively high traffic emissions in region. The highest daily mean level of NO₂ was also measured at Hurdal with 8.3 µg N/m³ on 13 December. The concentrations of NO₂ show an expected temporal pattern with a winter maximum and summer minimum especially at Hurdal (Figure 3.5). During winter, there is reduced vertical mixing and the atmospheric residence time is longer due to low photochemical activity.

The highest annual mean concentrations for the sum of nitrate (NO₃⁻ + HNO₃) and the sum of ammonium (NH₃ + NH₄⁺) were observed at Birkenes with 0.15 - 0.16 µg N/m³. Elevated levels were also observed at Tustervatn and Kårvatn, these sites are somewhat influence of agricultural activity in their regions.

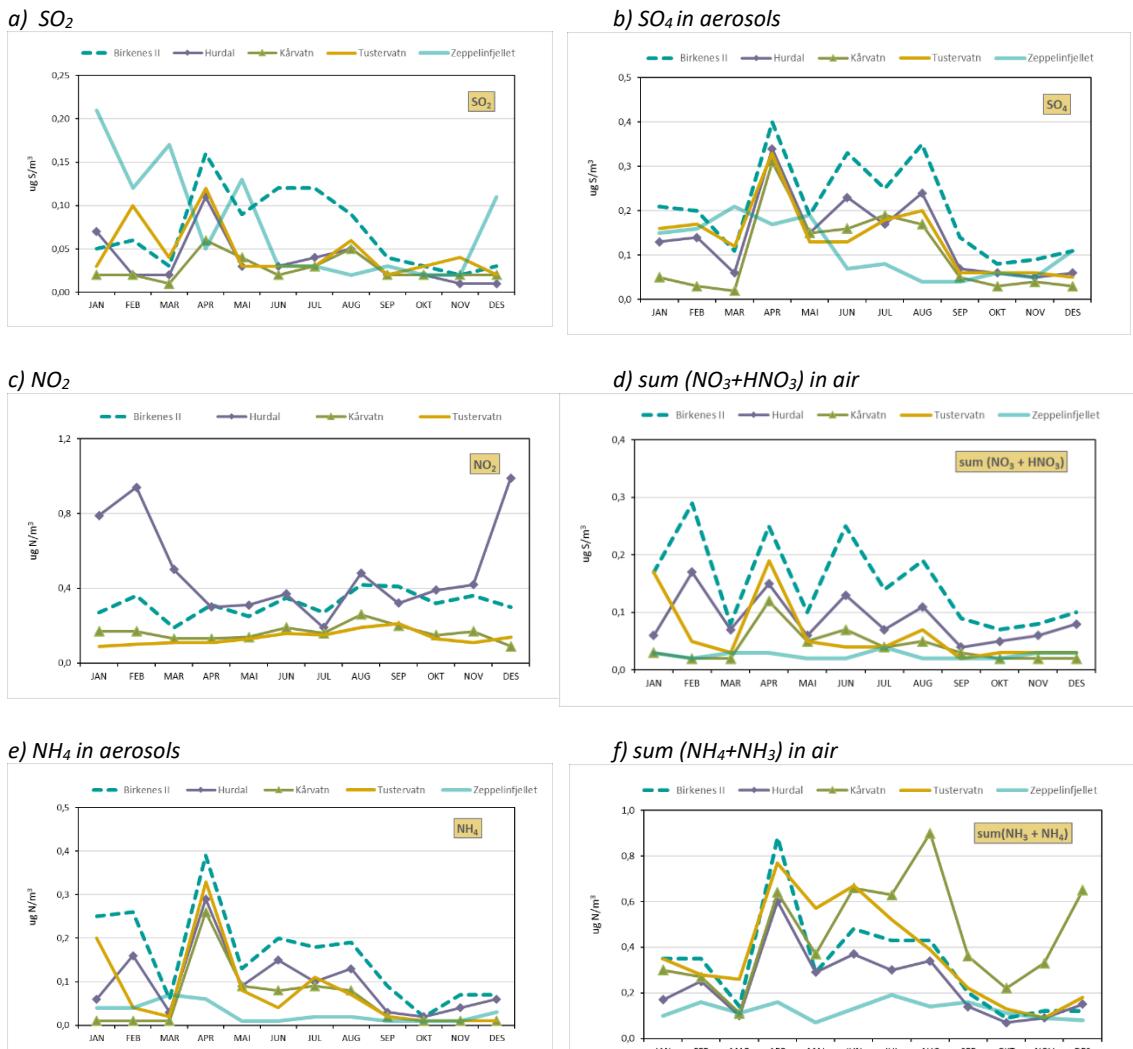

Figure 3.4: Monthly mean concentrations of sulfur- and nitrogen components in air at the five EMEP sites in Norway in 2019. Unit: $\mu\text{g}(\text{S or N})/\text{m}^3$.

3.1.3 Total deposition of sulfur and nitrogen

Table 3.9 and Figure 3.5: Present estimates of the total dry deposition of sulfur and nitrogen compounds and the measured wet deposition in the growing season from May to October (summer) and winter months from January to April and November to December. Dry deposition is calculated on the basis of the mean concentrations of SO_2 , SO_4^{2-} , NO_2 , sum of nitrate ($\text{NO}_3^- + \text{HNO}_3$), and sum of ammonium ($\text{NH}_3 + \text{NH}_4^+$) and deposition velocities given in the table text (Dovland and Eliassen, 1976; Dollard and Vitols, 1980; Fowler, 1980; Garland, 1978; Voldner and Sirois, 1986; Hicks et al., 1987).

For the sum of nitrate ($\text{NO}_3^- + \text{HNO}_3$), it is assumed that HNO_3 contributes with 25% and NO_3^- with 75%, whereas for the sum of ammonium ($\text{NH}_3 + \text{NH}_4^+$) NH_3 is presumed to contribute with 8% and NH_4^+ by 92% (Ferm, 1988). The dry deposition velocities of gases and particles are highly variable and uncertain quantities. The deposition of particles (SO_4^{2-} , NO_3^- , and NH_4^+) increases with wind speed and with the ground's roughness (forest coverage etc.). The deposition of gases (SO_2 , NO_2 , HNO_3 , and NH_3) depends on the biological activity of the vegetation and surface type (water, mountains, etc.). The deposition is for most gases far greater on wet surfaces than when the surfaces are dry. In winter, the deposition is small because of low biological activity, and

because the surface is often covered by snow and ice. The stable layer of air close to the ground in winter also reduces the transport of contaminants to the ground.

The wet deposition contribute most to the total deposition at all the sites on the mainland, for both nitrogen and sulfur, and the total deposition is highest in southern Norway (Figure 3.5 and Table 3.9). Dry deposition of sulfur contributes to the total deposition with 15-30% in summer and 3-7% in winter except at Svalbard where the dry deposition is higher due low precipitation amount. Dry deposition of nitrogen contributes between 13-34% in summer and 6-17% in winter to the total nitrogen load.

Table 3.9: Estimated dry deposition and measured wet deposition of sulfur and nitrogen at Norwegian background stations 2019.

Dry deposition = measured air concentrations · dry deposition velocity from literature

Dry deposition velocities used: SO₂: 0.1 cm/s (winter) - 0.7 cm/s (summer). SO₄: 0.2-0.6 cm/s, NO₂: 0.1-0.5 cm/s, HNO₃: 1.5-2.5 cm/s, NO₃: 0.2-0.6 cm/s, NH₄: 0.2-0.6 cm/s, NH₃: 0.1-0.7 cm/s. Sum nitrate = 25% HNO₃ + 75% NO₃. Sum ammonium = 8% NH₃ + 92% NH₄.

The %- values indicate the estimated contributed of dry deposition to the total deposition for winter (W) and summer (S) Summer = May - October, winter = January - April and November - December.

For Zeppelin, wet deposition is taken from Ny-Ålesund.

	Sulfur (mg S/m ²)						Nitrogen (mg N/m ²)

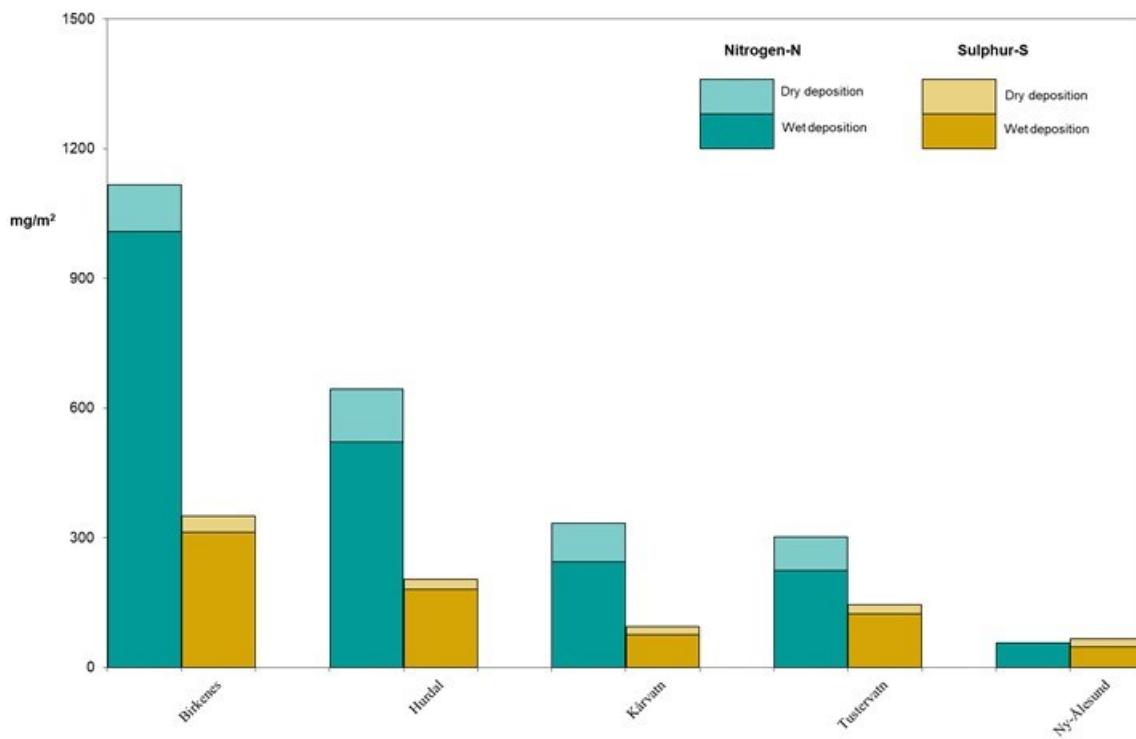

Figure 3.5: Total deposition (wet+ dry) of sulfur-S (SO_2 , SO_4^{2-}) and nitrogen-N (NO_2 , NH_4^+ , NH_3 , NO_3^- , HNO_3) at Norwegian background stations 2019.

3.2 Trends

An important goal of the monitoring programme is to measure the effectiveness of the protocols, i.e. the 1999 Gothenburg Protocol to Abate Acidification, Eutrophication and Ground-level Ozone (UN/ECE, 1999). Since Norway is downwind of the major emission sources in Continental Europe, the monitoring in Norway can give indications on the overall emission reductions in Europe. The objective of the multicomponent Gothenburg Protocol from 1999 was to reduce European emissions of sulfur by 63% in 2010 compared to 1990. Similarly, the target for nitrogen oxides and ammonia was a reduction of 41% and 17%, respectively. In 2012, the Gothenburg Protocol was revised, and new emissions targets were defined for 2020 with 2005 as the base year. The 27 EU countries have committed to the following emission reductions with the numbers for Norway in brackets; SO_2 : 59% (10%), NO_x : 43% (23%), nmVOC: 28% (40%), ammonia: 6% (8%) and $\text{PM}_{2.5}$: 22% (30%).

Figure 3.6-Figure 3.8 show the time series of annual mean concentrations of main ions in precipitation, in air and total deposition at selected sites in Norway with long time series. The concentration levels in 2019 were in general a bit lower or equal compared to 2018(Figure 3.6).

Table 3.10 and 3.11 shows the trends for four different periods, 1980-, 1990-, 2000-, and 2005-2019 for all sites with measurements in these respective periods.

For the statistical analysis, the non-parametric “Mann-Kendall Test” has been used on annual means for detecting and estimating trends (Gilbert, 1987). The Mann-Kendall test has become a standard method when missing values occurs and when data are not normally distributed. In parallel to this, the Sen’s slope estimator has been used to quantify the magnitude of the trends.

For sulfur, there has been a significant reduction at all the sites for all the sulfur components in air and precipitation from both 1980 and 1990 to 2019. Since 1980, the content of sulfate in precipitation in Norway has decreased by 77-98%. The reductions in airborne concentrations of sulfate have been similar, between 86% and 93% at the Norwegian mainland, while for sulfur dioxide the trend is almost 100%. The calculated linear trend for this long period gives reductions higher than 100%, which illustrates the problem of assuming linearity when the trend is higher in one part of the period. Somewhat lower reductions are observed at the Zeppelin Observatory; 89% for sulfur dioxide and 68% for sulfate, Table 3.10.

The reductions since 1990 have been between 65% and 88% (sulfate in precipitation), 75-95% (sulfur dioxide) and 72-82% (sulfate in air) for the sites at the mainland. From 2000, all sites except Tustervatn have observed a significant reduction of sulfate in precipitation between 39% and 71%. For sulfur dioxide and sulfate in air, there are significant reductions at all mainland sites (except Kårvatn for SO₂) with 54-61% and 50-63%, respectively. Most of the sites with trends from 2005 show an observed sulfur reduction in precipitation close to the target of 59% emission reductions, which is to be reached within 2020. For sulfate in air the trends in between 40-50%.

The nitrate and ammonium concentrations in precipitation have significantly decreased at most sites south of Kårvatn, 43-55% for nitrate and 50-67% for ammonium since 1980. The air measurements did not start as early as the ones for precipitation, thus trend analysis for these have only been done from 1990.

For nitrate in precipitation, most sites show a significant decrease between 27% and 53% from 1990 to 2019. Most of the sites also show a decrease of ammonium, but some show a significant increase. There is a decrease in the observed ammonium from 1990 (but not from 2000) and a decrease from 1990 for sum ammonium at three of the four sites at the mainland, around 50%; while for sum nitrate only one site show a significant decrease. For nitrogen species, the annual variations vary somewhat more than for sulfur species due more influence of changes in local emissions, which can make it more difficult to detect trends in long range transport of air pollution.

The NO₂ concentration has decreased at all four sites, between 40-69% from 1990 and 39-47% from 2000. The observed reductions in concentration levels of sulfur and nitrogen species are in agreement with reported downwards trends in pollutant emissions in Europe (Tørseth et al., 2012; Colette et al., 2016).

Calcium is significantly reduced at most sites since 1980, which is consistent with emission reductions from anthropogenic sources in Europe (Hellsten et al., 2007). However an increase in calcium at three sites from 2000, which is not consistent for the 2005-2019 period, indicates that there are variations in the contribution from mineral dust influencing the trends. The contribution of sea salts are influenced by meteorological conditions and vary from year to year. A significant reduction is seen at Treungen from 1980-2019, but only at Ny Ålesund there is a consistent decrease in seas salt ions (Mg²⁺ and Ca²⁺) for all the periods since 1990.

Table 3.10: Trends in annual mean concentrations of inorganic ions in precipitation. Only significant trends are shown ($p=0.05$). Shaded area means not available data, while the signs indicate increase or decrease in percent change for the whole period.

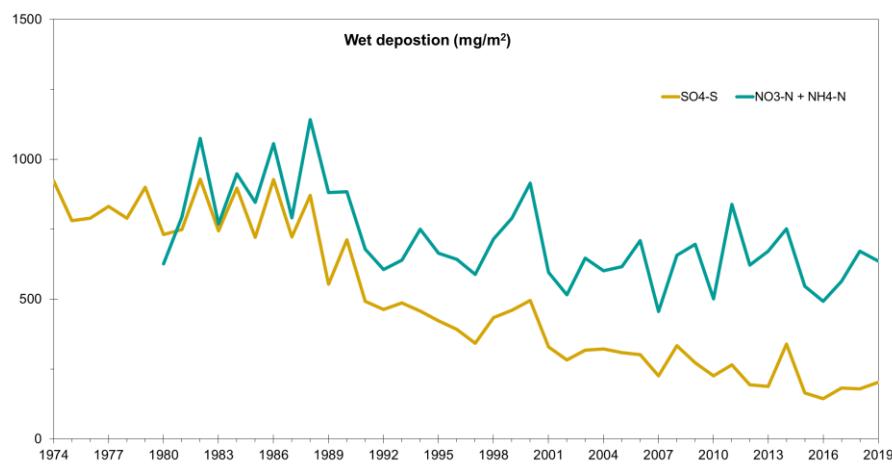

Figure 3.6: Average volume weighted annual mean concentrations (a), precipitation amount (b) and wet deposition (c) for sea salt corrected sulfate, nitrate and ammonium at five representative sites in southern Norway (Birkenes, Vatnedalen, Treungen, Gulsvik and Løken), 1974-2019.

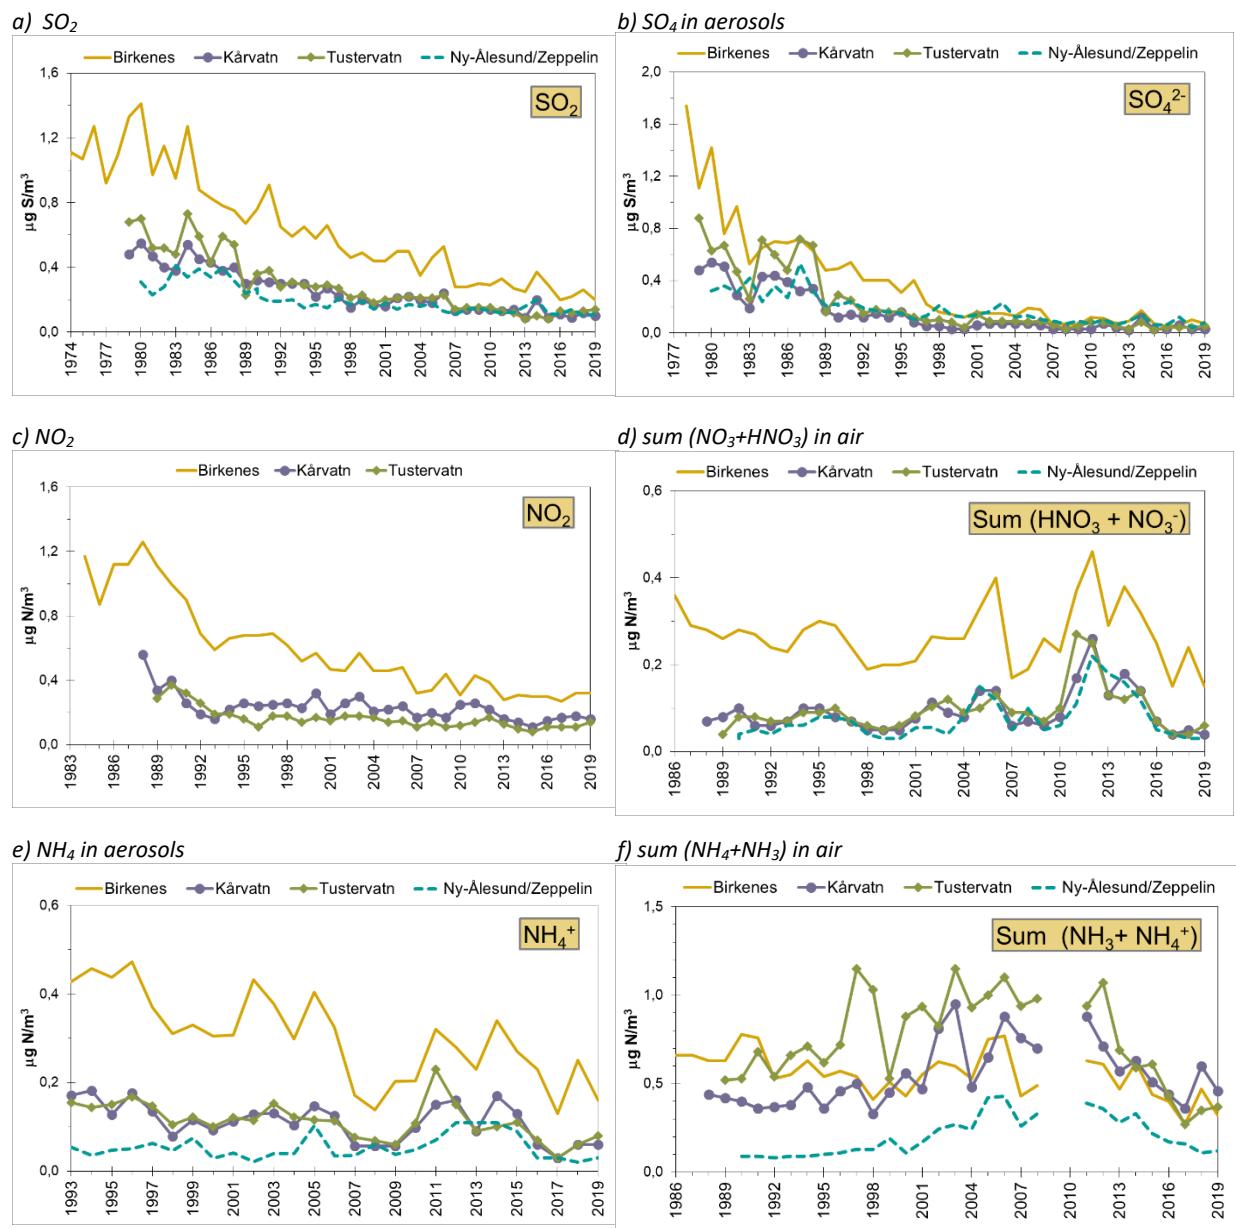

Figure 3.7: Annual mean concentrations of sulfur and nitrogen components in air at four Norwegian EMEP sites, 1973-2019.

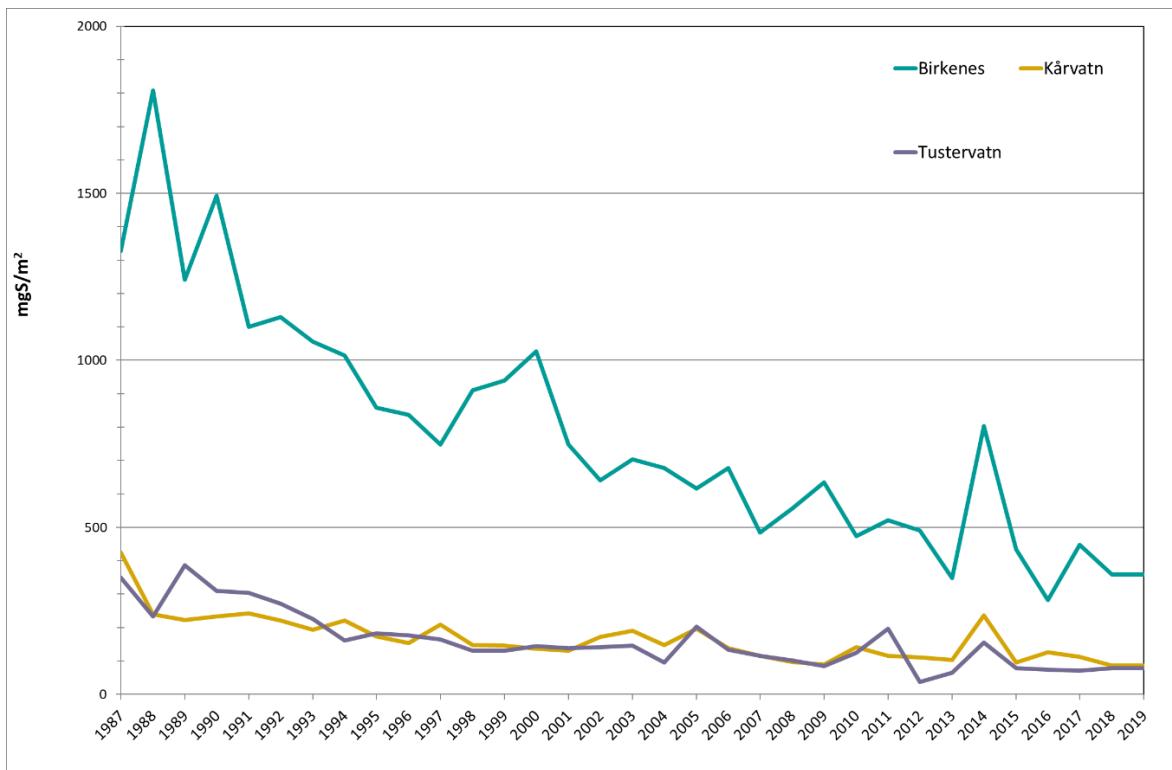

Figure 3.8: Trends in total deposition (wet + dry) of sulfur at three Norwegian EMEP sites, 1987–2019.

3.3 Summary

For most of the main inorganic components, the highest annual mean concentrations in 2019 were measured at Birkenes, which is the station in Norway most affected by long-range transport of pollutants. However, some inland sites are influenced by regional agricultural activities and experience somewhat higher ammonium concentrations. For NO₂, the highest levels are seen in Hurdal, which is influenced by the relatively high traffic emission in the region. Karpbukt, situated close to the Russian border, experience high sulfate-concentrations due to emissions from the smelters in Kola Peninsula. The highest wet deposition loads of sulfate, nitrogen components and strong acid occurred along the coast from Aust-Agder to Hordaland.

The concentration levels in 2019 were in general a bit lower compared to 2018. In a longer perspective, there are large reductions in sulfur in all parts of Norway, since 1980 more than 90%, since 1990 around 70% (depending on the compound), and since 2000 about 50-60%, while from 2005 most sites show trends in sulfate in precipitation close to the European target of 59% emission reductions set by the Gothenburg protocol to be reached within 2020.

Nitrate and ammonium concentrations in precipitation have decreased significantly at most sites in southern Norway, around 50% for both components since 1980, and somewhat less from 1990. The NO₂-concentration has also decreased significantly of the order of 40-69% from 1990. These observed reductions are in line with reported emission reduction at the European continent (Colette et al, 2015), although most sites show lower trends in oxidized nitrogen than the target of 43% reductions in NO_x emissions set by the Gothenburg protocol from 2005.

4 EC and OC

4.1 Introduction

Monitoring of Elemental Carbon (EC) and Organic Carbon (OC) in PM₁₀ and PM_{2.5} takes place at three rural background sites: The Birkenes Observatory and the Hurdal and Kårvatn sites. The time series at the Birkenes Observatory dates back to 2001 and to 2010 at Hurdal and Kårvatn. For 2019, OC and EC measurements in PM₁₀ for the remote Arctic site Zeppelin Observatory was included.

Annual and monthly mean concentrations of EC and OC in PM₁₀ and PM_{2.5} for 2019 are shown in Table A.1.35; whereas annual mean concentrations for EC and OC in PM₁₀ and PM_{2.5} for the period 2001 – 2019 are listed in Table A.1.36::

Incidences of PM_{2.5} > PM₁₀ on a monthly basis are typically due to a different number of samples for the two size fractions, but for low levels, measurement uncertainties can have an influence as well, in particular for EC. OC in PM_{10-2.5} is derived from the observed values of OC in PM₁₀ and PM_{2.5} and is discussed in the report for a better understanding of the observed data, but is not listed in any table. Background information on the carbonaceous aerosol (here: EC and OC) can be found in Annex 3.

4.2 Concentrations of OC in PM₁₀, PM_{2.5} and PM_{10-2.5}

The annual mean concentration of OC in PM₁₀ (0.69 – 1.23 µg C/m³) and PM_{2.5} (0.53 – 0.71 µg C/m³) at Norwegian rural background sites are amongst the lowest in Europe. Fine fraction OC (58 – 77%) was the major fraction of OC in PM₁₀ at all sites on an annual basis. This is as expected as the major sources, primary emissions from combustion of fossil fuel and biomass and secondary particle formation from biogenic and anthropogenic precursors typically generate fine aerosol particles. Coarse fraction OC occasionally dominates on a monthly basis. This is typically observed for the second half of the vegetative season and is attributed to the presence of primary biological aerosol particles (PBAP), such as e.g. fungal spores.

The annual mean concentration of OC in PM₁₀ at Hurdal was 30-80% higher than at Birkenes and at Kårvatn. The difference in concentration was largely explained by the coarse fraction of PM₁₀. Coarse OC is mainly associated with PBAB of local to regional origin. The measurements do not allow for explaining why the source strength is so much higher at Hurdal compared to the other sites, and we are left with concluding that it reflects variability in the local vegetation. We speculate that the more densely populated and anthropogenic influenced region surrounding the Hurdal site is the main explanation for the observed increment of fine fraction OC. This is also in line with the higher NO₂ and EC concentrations seen for this site, which has been explained by high emissions from vehicular traffic in this region (see Chapter 3.1.2)

There was a seasonal variability with increased levels of OC in summer (April - September) compared to winter (October - March) for all sites and size fractions; the seasonality being more pronounced for the coarse than the fine fraction, and with large variability between sites. This reflects increased levels of Secondary Organic Aerosols (SOA), and Biogenic Secondary organic Aerosols (BSOA) in particular, contributing to the fine fraction, and PBAP contributing to the coarse fraction in the vegetative season (See Yttri et al. 2011 a, b). The highest levels of fine OC were seen in April, which experienced temperatures high above normal and precipitation below normal at all sites, and at Birkenes the monthly mean exceeded 2 µg C m⁻³, which rarely occurs. Several sources contributed to the elevated levels observed in April, including emissions from wildfires in Eastern Europe in the last week of April, as confirmed by unusually high levoglucosan levels at the actual time of the year at Birkenes. Indeed, a weekly mean OC concentration exceeding 4 µg C m⁻³ was seen for two of the weeks in April. The April

episode caused elevated concentration for many species across several sites in Norway and is described in more details in Chapter 7.

There was a certain level of covariance between sites both with respect to seasonality and high concentration episodes. This was driven by fine fraction OC and was particularly pronounced for the two southernmost sites, Birkenes and Hurdal. Such seasonal covariance is driven by climatological factors. As an example, temperature is decisive for the formation of SOA and pollen release in summer as well as for domestic heating in winter. Episodes of long-range transported air pollution is well known to affect large regions. Finally, prolonged sampling time (here: weekly) could also contribute to mask differences between sites.

The annual mean concentration of OC in PM_{2.5} was within -SD of the long-term mean at all sites, whereas coarse OC was higher than +SD at Birkenes and Hurdal and within -SD at Kårvatn. Consequently, OC in PM₁₀ was within +SD at Birkenes and Hurdal and within -SD at Kårvatn. The annual mean coarse OC observed at Hurdal and Birkenes in 2019 was the highest and second highest seen so far. Consequently, OC in PM₁₀ at these two sites was only marginally lower than the previous year despite that fine OC was rather low.

The annual mean OC concentration at the Zeppelin Observatory was 7 - 12 times lower than that observed at rural background sites on the Norwegian mainland. The seasonality of OC largely resembled that of rural sites at the Norwegian mainland, except that the increased level in the vegetative season associated with BSOA and PBAP started 1 - 2 months later. The biomass burning tracer levoglucosan was elevated in the heating season but also in late summer and early fall, showing the influence of residential wood burning and wild fires, respectively.

4.3 Concentrations of EC in PM₁₀ and PM_{2.5}

The annual mean concentration of EC in PM₁₀ (0.05 – 0.11 µg C/m³) and PM_{2.5} (0.05 – 0.10 µg C/m³) at Norwegian rural background sites are amongst the lowest in Europe. EC results from incomplete combustion of fossil fuel and biomass and emissions are thus almost exclusively associated with the fine fraction of PM₁₀. EC levels at Hurdal were 25 - 40% higher than at Birkenes and 100 – 120% higher than at Kårvatn, considering both the PM₁₀ and PM_{2.5} size fractions. The wide ranges and differences between size fractions are misleading and result from the very low levels and “decimal-issues”. As argued for OC in Chapter 4.2, we assume that the higher levels of EC at Hurdal is caused by the more densely populated and anthropogenic influenced region surrounding the site; albeit crude, EC is regarded as a tracer of anthropogenic activity. EC was a minor contributor to the total carbon (TC) concentration; i.e., 7 – 8% (PM₁₀) and 9 – 12% (PM_{2.5}). The annual mean EC/TC ratio was within ±SD of the long-term EC/TC mean at all sites, except for PM₁₀ at Birkenes where it was just below -SD.

The very high monthly mean seen for April explains the somewhat deviating seasonality of EC compared to previous years, causing a slightly higher mean for summer than in winter at Birkenes, marginally higher levels in winter than in summer at Hurdal, and noticeably higher levels in summer than in winter at Kårvatn. A mix of EC from fossil fuel combustion and from agricultural fires, a certain contribution from residential heating cannot be excluded, contributed to the high monthly mean for April. The contribution of biomass burning to EC (and OC) have been estimated based on levoglucosan measurements (Chapter 4.6).

The annual mean concentration of EC was equal to or within –SD of the long-term mean at all sites.

The annual mean EC concentration at the Zeppelin Observatory was 5 - 11 times lower than that observed at rural background sites on the Norwegian mainland. EC was elevated in winter compared to summer, and more pronounced than at the rural background sites. The annual mean EC/TC ratio at

Zeppelin (9%) was slightly higher than calculated for rural background sites. This finding was most pronounced in winter and spring, and may reflects issues such as different source regions, source composition and removal processes.

4.4 Relative contribution of EC and OC to PM

The relative contribution of OC to PM_{10} (20 – 27%) and $\text{PM}_{2.5}$ (23 - 28%) annually was rather similar, and for Birkenes somewhat lower than for the two other sites. The OC fraction was higher in summer than in winter, but less pronounced for $\text{PM}_{2.5}$ than for PM_{10} . The relative contribution of OC to $\text{PM}_{10-2.5}$ was 13 - 27% on an annual basis, and more pronounced in summer (21 – 33%) than in winter (4 – 13%).

EC accounted for 1.7 – 2.4% of PM_{10} annually and somewhat higher for $\text{PM}_{2.5}$ (2.6 – 3.7%), reflecting that EC is associated with fine aerosol particles. EC was more abundant in the winter-time aerosol (1.8 – 3.7% for PM_{10} and 3.5 – 5.4% for $\text{PM}_{2.5}$) than the summer-time aerosol (1.4 – 1.6% for PM_{10} and 2.4 – 2.6% for $\text{PM}_{2.5}$).

4.5 Trends for concentrations of EC and OC

The Mann Kendall method described in Chapter 3.2 was used for trend analysis of concentrations of EC and OC. The shorter time series for the sites Hurdal and Kårvatn (9 years) allow for an assessment of the Birkenes site only (Table 4.1). The time series of OC in PM_{10} , $\text{PM}_{2.5}$ and $\text{PM}_{10-2.5}$, and that of EC in PM_{10} and $\text{PM}_{2.5}$, at the Birkenes Observatory are shown in Figure 4.1.

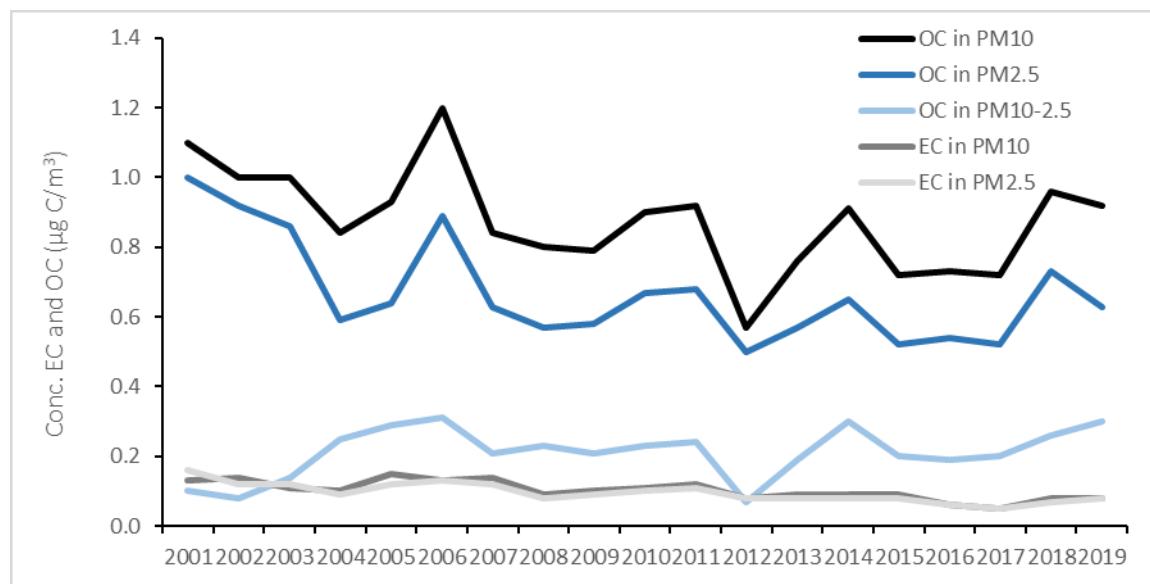

Figure 4.1: Annual mean time series of EC and OC, as observed at the Birkenes Atmospheric Observatory (2001 – 2019).

There was a statistically significant downward trend for the annual mean concentration of OC in both PM₁₀ (-20%) and PM_{2.5} (-31%) at Birkenes for the period 2001 – 2019. EC showed a statistically significant downward trend for both PM₁₀ (-49%) and PM_{2.5} (-55%) for 2001 – 2019.

Table 4.1: Trends in annual mean mass concentration of OC, EC and TC in PM₁₀ (2001 - 2019) and PM_{2.5} (2001 - 2019) using Mann-Kendall test and Sen slope estimates; significant level is set to 0.05.

Site	PM ₁₀	% change	PM _{2.5}	% change
Birkenes				
OC	*	-20%	*	-31%
EC	*	-49%	*	-55%
TC	*	-31%	*	-36%

Trends are calculated for time series extending 10 full years.

No statistically significant upward or downward trends was observed for OC to PM for neither of the size fractions. A decrease in the relative contribution of EC to PM₁₀ (-25%) was observed for 2001 – 2019 at Birkenes.

4.6 Concentrations of levoglucosan, mannosan and galactosan in PM₁₀

Measurements of levoglucosan, mannosan and galactosan in PM₁₀ takes place at the Birkenes Observatory, and is used to estimate the contribution of biomass burning to the carbonaceous aerosol (here: OC and EC) and to PM.

The annual mean concentration of levoglucosan in PM₁₀ observed at the Birkenes Observatory was 8.3 ng m⁻³ (Table 4.2). The seasonality was pronounced with higher levels in the heating season. Low levoglucosan levels in summer may partly reflect increased degradation by the OH radical, but higher emissions from residential wood burning in winter compared to summer explains most of the seasonality. The elevated concentrations in the beginning and the end of April are associated with long range transport from agricultural fire emissions in the Belarus and Western parts of Russia (Se Chapter 7).

A seasonally consistent levoglucosan/mannosan ratio indicates that emissions from one source (residential wood burning) prevails, and supports one emission ratio when estimating OC and EC levels from levoglucosan (here: 12.7 for OC in PM₁₀, 11.1 for OC in PM_{2.5}, and 1.96 for EC (Yttri et al., in prep.)). Some influence from wild and agricultural fires in the vegetative season is likely, but the magnitude of these sources remains speculative except for such major episodes as seen in April.

We estimate that biomass burning contributed 11-17% to OC and 21% to EC, annually, considering both PM₁₀ and PM_{2.5}. The fraction attributed to biomass burning in winter was 40% for OC and 33-37%-56% for EC, whereas it was ≤2.5% (OC) and <5% (EC) in summer, considering both size fractions. Spring and fall are transition seasons with relative contributions lower than in winter and higher than in summer.

Ongoing studies suggest that long-range transported (LRT) air pollution from continental Europe explains elevated biomass burning aerosol levels observed at the Birkenes Observatory. LRT is decisive not only for episodes of high concentrations, but also largely explains the mean concentration.

Table 4.2.: Annual mean concentrations of levoglucosan, mannosan and galactosan in PM₁₀ at Birkenes for 2017-2019. Seasonal mean concentrations for 2019. Unit: ng m⁻³.

Year		Levoglucosan	Mannosan	Galactosan
2017	Annual	8.2	1.3	0.32
2018	Annual	9.8	1.6	0.39
2019	Annual	8.3	1.4	0.29
	Winter	16.7	2.7	0.61
	Spring	8.3	1.2	0.26
	Summer	1.3	0.3	0.05
	Fall	6.9	1.3	0.23

Winter = DJF; Spring = MAM; Summer = JJA; Fall = SON.

4.7 Summary

Observed annual mean concentrations of carbonaceous aerosol in the Norwegian rural background environment are amongst the lowest in Europe ($OC < 1.2 \mu\text{g C m}^{-3}$ and $EC < 0.11 \mu\text{g C m}^{-3}$), and a statistically significant downward trend was observed for OC (-20 - -31%) and EC (-49 - -55%) in PM₁₀ and PM_{2.5} for the period 2001 – 2019.

Measurements complementary to OC and EC are needed for an assessment of sources. Previous source apportionment studies of the carbonaceous aerosol in the Norwegian rural background environment show that natural sources, biogenic secondary organic aerosol (BSOA) and primary biological aerosol particles (PBAP), dominate the organic aerosol in summer, whereas anthropogenic sources, fossil fuel and biomass burning, dominate in winter. With a few exceptions, EC can be considered exclusively anthropogenic, as also agricultural and wild fires as seen in April 2019 typically are initiated by anthropogenic activity. Estimates based on levoglucosan measurements suggest that biomass burning contributed 11-17% to OC and 21% to EC at the Birkenes Observatory annually, considering both PM₁₀ and PM_{2.5}, and 40% for OC and around 33-37% for EC in winter.

5 Particulate matter, mass concentrations

5.1 Introduction

Monitoring of the PM₁₀ and PM_{2.5} mass concentration takes place at three rural background sites; the Birkenes Observatory and the Hurdal and Kårvatn sites. The time series at Birkenes dates back to 2000/1, whereas measurements were initiated in 2010 at the two other sites. At Birkenes, high time resolution measurement of the aerosol size distribution for the size range 0.01 – 10 µm, was initiated in 2010, whereas high time resolution measurements of PM₁₀ started in 2017.

Annual and monthly mean mass concentrations of PM₁₀, PM_{10-2.5} and PM_{2.5} for 2019, obtained by gravimetric measurements, are shown in Table A.1.37:, whereas annual mean mass concentrations of PM₁₀, PM_{10-2.5} and PM_{2.5} for the time period 2000 – 2019 are listed in Table A.1.38:. Time series of PM₁₀ and PM_{2.5} for 2019 are shown in Figure 5.1. Note that PM_{10-2.5} is derived from the observed values of PM₁₀ and PM_{2.5}; i.e. the difference between PM₁₀ and PM_{2.5}. Incidences of PM_{2.5} > PM₁₀ and ΣPM_{2.5}, PM_{10-2.5} ≠ PM₁₀ on a monthly basis are typically due to a different number of samples for PM₁₀ and PM_{2.5}, but for low levels measurement uncertainties can have an influence as well. Annual means of aerosol particle number (*N*) concentrations for ultrafine (0.02 < D_p < 0.1 µm), accumulation mode (D_p = 0.1 - 1.0 µm) and coarse mode (D_p = 1.0 – 10 µm) particles, are shown in Table 5.4. 24 hours mean concentrations of PM₁₀ derived from high time resolution measurements, were used to asses violation of national and international limit values and air quality guidelines. Background information on PM can be found in Annex 3.

5.2 PM₁₀, PM_{2.5} and PM_{10-2.5} concentrations

The annual mean mass concentration of PM₁₀ (2.9 – 4.6 µg/m³) and PM_{2.5} (1.9 – 2.7 µg/m³) at the Norwegian rural background sites are amongst the lowest in Europe. PM_{2.5} was the major fraction of PM₁₀ at all sites on an annual basis, accounting for 59% at Birkenes and Hurdal and 66% at Kårvatn. PM_{10-2.5} was occasionally the major fraction of PM₁₀ on a monthly basis, and is typically attributed to natural sources, such as sea salts, primary biological aerosol particles (PBAP), and mineral dust.

The PM₁₀ and PM_{2.5} annual means were within –SD of the long-term mean at all sites. At Birkenes, the PM_{10-2.5} annual mean was within -SD of the long-term mean, whereas it was slightly higher than +SD at Hurdal and Kårvatn. Note that the measurements for Hurdal and Kårvatn dates back to 2010, whereas measurements at Birkenes were initiated in 2000/2001.

The PM₁₀ annual mean was equally high at Birkenes and Hurdal in 2019, unlike previous years when the PM₁₀ level typically has been slightly higher at Birkenes. This has been explained by the somewhat higher PM_{10-2.5} fraction at Birkenes, as well as a higher PM_{2.5} fraction when compared to Kårvatn, but this gap has narrowed substantially over the last 10 years of sampling. The higher PM_{10-2.5} fraction at Birkenes is largely attributed to the sea salt aerosol, which was 3 times higher compared to the two other sites, reflecting its proximity to the coast (20 km). It can also be speculated that a larger fraction of NO₃⁻ reside in the coarse fraction of PM₁₀ at Birkenes, following from the reaction between gaseous HNO₃ and coarse mode NaCl. Coarse fraction organic matter (OM), dominated by PBAP, was 1.7 times higher at Hurdal compared to Birkenes, thus counteracting some of the discrepancy attributed to the lower sea salt aerosol contribution when compared to Birkenes

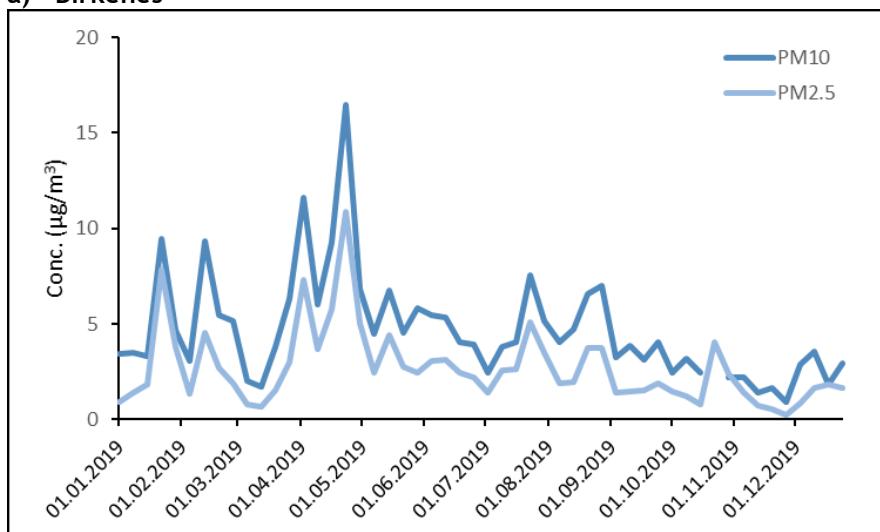

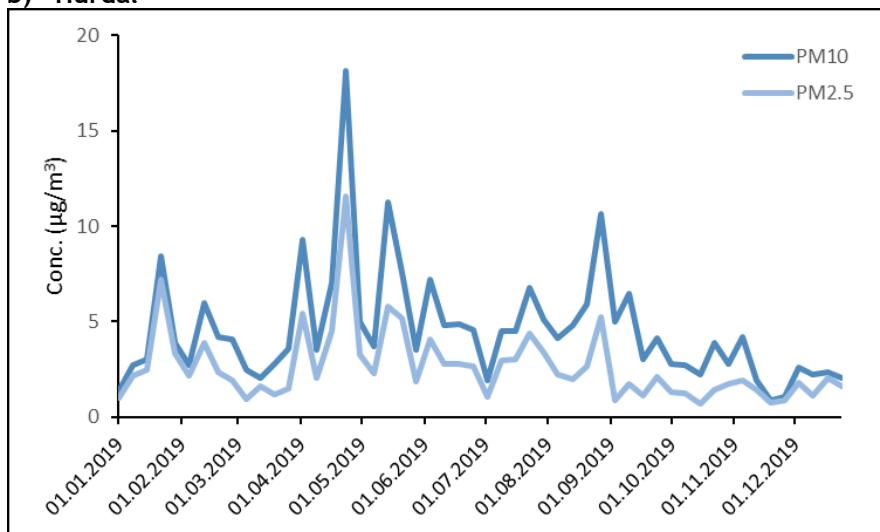

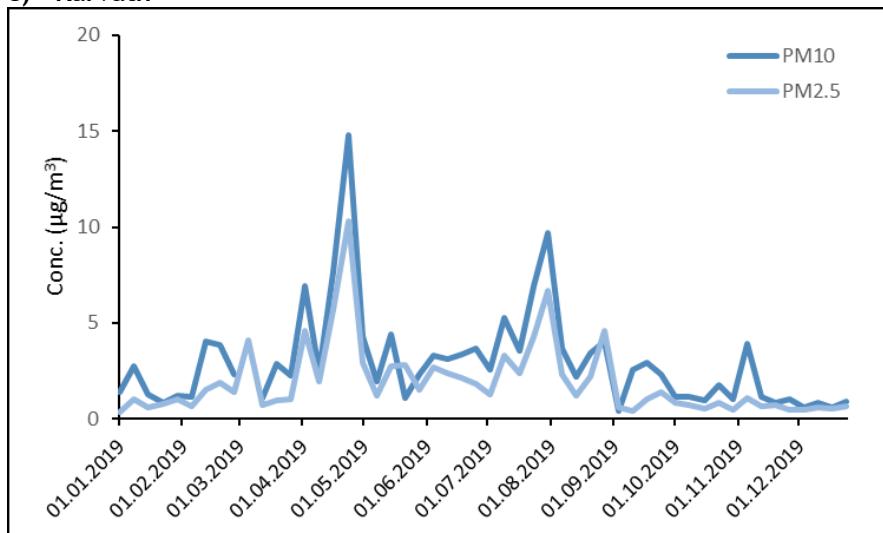

a) Birkenes**b) Hurdal****c) Kårvatn**

Figure 5.1: Time series of PM₁₀ and PM_{2.5} mass concentration for Birkenes (a), Hurdal (b) and Kårvatn (c) for 2019. Unit $\mu\text{g}/\text{m}^3$. Note that the time series have been harmonized in time for comparability; i.e. they all start on the same date (01.01.2019).

The annual mean PM_{2.5} concentration was equally high at Hurdal and Birkenes but noticeably higher compared to Kårvatn. The difference with respect to Kårvatn is explained by lower levels of OM, EC and secondary inorganic aerosol constituents (SIA) (i.e. SO₄²⁻, NO₃⁻ and NH₄⁺, typically residing in the fine fraction of PM₁₀). SIA levels were higher at Birkenes than at the two other sites, particularly compared to Kårvatn, even though a larger fraction of SIA, and NO₃⁻ in particular, likely is associated with the coarse fraction of PM₁₀ at Birkenes.

The highest PM₁₀, PM_{2.5} and PM_{10-2.5} monthly means were observed in April at all sites. Southerly air masses caused temperatures high above normal and precipitation below normal at all sites and facilitated transport of air pollution from continental Europe, formation of secondary organic pollutants, as well as an early onset of PBAP emissions. Emissions from wild and agricultural fires in Belarus and western parts of Russia contributed substantially to PM levels in April (See Chapter **Error! Reference source not found.**), as did mineral dust from the African continent. Indeed, we estimated a mineral dust concentration of 3.1 µg m⁻³ for April, which was 5 times higher than the estimated annual mean (0.6 µg m⁻³).

The 2019 PM₁₀ and PM_{2.5} time series at Birkenes were episodic (Figure 5.1), reflecting episodes of long-range atmospheric transport, but also emissions from local to regional scale sources, such as e.g. sea spray. Some of these periods observed at Birkenes were also seen at Hurdal, and to some extent at Kårvatn. Weekly mean concentrations exceeding 10 µg m⁻³ were observed at all sites both for PM₁₀ and PM_{2.5}. The highest weekly mean (19.6 µg m⁻³) was observed at Hurdal, but maximum concentrations at Birkenes (17.8 µg m⁻³) and Kårvatn (15.9 µg m⁻³) were almost equally high. The PM₁₀ concentration exceeded 10 µg m⁻³ at Birkenes for four weeks, three at Hurdal, and two at Kårvatn. Secondary inorganic aerosol (SIA) was the major fraction of PM₁₀ for two of the four samples for which PM₁₀ exceeded 10 µg m⁻³ at Birkenes, whereas organic matter (OM) dominated two samples. Notably, mineral dust made a 24 – 27 % contribution for the two samples dominated by OM, appearing in spring. At Hurdal and Kårvatn, the highest weekly means were all dominated by OM, and for one of the weeks coarse OC was more abundant than fine OC.

The fine fraction was most abundant for most of the samples with a PM₁₀ level exceeding 10 µg m⁻³, the coarse fraction was higher for one of the samples, equally high for one, and marginally lower for one. This reflects a noticeable influence of coarse fraction PM as well, originating mainly from sea salt aerosol, PBAP, mineral dust and NO₃⁻.

Source apportionment studies (Yttri et al., 2011a, b) show that natural sources dominate OM in PM₁₀ at Norwegian rural background sites in summer, with biogenic secondary organic aerosol (BSOA) being the major source followed by primary biological aerosol particles (PBAP), whereas wild fires occasionally make a noticeable contribution.

5.3 Trends

The Mann Kendall method described in Chapter 3.2 was used for trend analysis of PM concentrations. Only time series extending 10 years was assessed; i.e. Birkenes (Table 5.1). A statistically significant downward trend was observed for the annual mean concentration of PM_{10} at Birkenes, corresponding to a decrease of -33% from 2000 to 2019 (-34% for the period 2001-2019). The observed downward trend for $PM_{2.5}$ was also statistically significant, corresponding to a decrease of -45% from 2001 to 2019. No significant trend was calculated for $PM_{10-2.5}$.

*Table 5.1: Trends in annual mean mass concentration of PM_{10} (2000 - 2019) and $PM_{2.5}$ (2001 – 2019) at Birkenes) using Mann-Kendall test and Sen slope estimates;

5.4 Compliance with EU limit values and Air-Quality Guidelines for PM₁₀ and PM_{2.5}

The EU annual limit value for PM₁₀ and PM_{2.5} (See Table 5.2 for EU limit values and Air-Quality Guidelines for PM₁₀ and PM_{2.5}) was far from being violated at any of the three sites in 2019; the highest annual mean PM concentrations observed being approximately 11% of the annual limit value. This was also the case when compared to the WHO Air-Quality Guidelines (AQG); the highest annual mean concentrations accounting for 23 – 27% of the annual AQG.

New national limit values for PM₁₀ and PM_{2.5} were implemented 1st of January 2016 (Table 5.2). These are less stringent than the WHO AQG, and thus far from being violated at any of the three sampling sites in 2019. The National Air-Quality Guidelines (FHI, 2013) are more stringent than the WHO's with respect to PM_{2.5}, still, the highest annual mean observed for PM₁₀ and PM_{2.5} in the Norwegian rural background environment in 2019, accounted for no more than 23% and 34% of the PM₁₀ and PM_{2.5} National AQG, respectively.

The highest 24-hour mean PM₁₀ concentration observed for 2019 was 24.0 µg m⁻³, and thus did not violate any limit values or AQG. No 24-hour measurements are performed for PM_{2.5}. Unfortunately, the instrument underwent critical repair when the highest weekly means for PM₁₀ and PM_{2.5} were observed at Birkenes.

Table 5.2: EU limit values and Air-Quality Guidelines for PM₁₀ and PM_{2.5}.

	24-hours	Annual
EU limit values		
PM ₁₀	50 µg/m ³ (\leq 35 days yr ⁻¹)	40 µg/m ³
PM _{2.5}		25 µg/m ³

5.5 Chemical composition of particulate matter

EC and OC were measured in the PM₁₀ and PM_{2.5} size fractions at the Birkenes, Hurdal and Kårvatn sites, whereas the major inorganic anions (SO₄²⁻, NO₃⁻, Cl⁻) and cations (Ca²⁺, Mg²⁺, K⁺, Na⁺, NH₄⁺) were obtained from open filter face samplers with a cut-off size exceeding 10 µm equivalent aerodynamic diameter (EAD). However, most of these species typically reside within the PM₁₀ fraction. Occasionally, sea salt aerosol larger than PM₁₀ could be collected, i.e. during stormy weather conditions at Birkenes, at a southerly wind direction. The data obtained from the monitoring programme appear to be well suited for a mass closure of PM₁₀, except that species representing mineral dust are not included. For 2014 - 2019, the PM₁₀ filter samples collected at Birkenes were analyzed with respect to iron (Fe), which allows for calculating/estimating the mineral dust content. Mass closure of PM_{2.5} and PM_{10-2.5} would include a larger degree of uncertainty than for PM₁₀, as default assumptions would have to be made according to the size distribution of the inorganic species analyzed, of which the largest uncertainty would be associated with that of NO₃⁻, thus this is not performed.

The annual mean chemical mass composition of PM₁₀ is shown in Figure 5.3. The speciated mass explained 55 – 74% of the annual mean concentration of PM₁₀ for the three sites, approaching full mass closure (73 – 89%) when allowing for other elements than carbon for OC and EC. The PM₁₀ SIA fraction (and levels) was noticeably higher at Birkenes (29%) compared to Hurdal (18%) and Kårvatn (17%), reflecting the proximity of Birkenes to important SIA-precursor emission source regions in continental Europe. SO₄²⁻ was the most abundant single (SIA) species at all sites, and at Birkenes and Hurdal it was approximately equally high as the sum of NO₃⁻ and NH₄⁺, whereas it was almost twice as high at Kårvatn.

Converting OC to OM using a factor of 1.7 (Yttri et al., 2007) made OM more than twice as abundant as SIA at Hurdal (46%) and Kårvatn (40%), whereas OM only was slightly higher at Birkenes (34%). The higher relative contribution of EC at Hurdal (2.2%) compared to Birkenes (1.7%) and Kårvatn (1.5%) is consistent with previous years, likely reflecting the more densely populated and anthropogenic influenced region surrounding the Hurdal site.

Situated approximately 20 km from the coastline, Birkenes experienced a substantial 21% sea salt aerosol contribution to PM₁₀, which is 2 – 3 time higher than at Kårvatn (12%) and Hurdal (6.4%).

Based on Fe measurements in PM₁₀ at Birkenes and knowledge about mineral dust composition in Europe (Alastuey et al., 2016), an annual mean mineral dust concentration of 0.6 µg m⁻³ was estimated for Birkenes for 2019, corresponding to 13% of PM₁₀ annually. This was identical to the previous year but noticeably higher than for 2014 - 2017 (7 - 9%), and allows for a complete mass closure of PM₁₀ for 2019; i.e. when using OM for mass closure. Mineral dust levels and its relative contribution to PM₁₀ peaked in spring and summer, typically accounting for 10 – 16% of PM₁₀, except for April which experienced a substantial 28% contribution.

Statistically significant up- or downward trends were observed for fractions of SO₄²⁻, NO₃⁻, EC and sea salt aerosol particles (Table 5.3), and all for PM₁₀. The SO₄²⁻ and EC fractions of PM₁₀ both had a statistically significant downward trend for the period 2001 - 2019, being more pronounced for SO₄²⁻ (-34%) than for EC (-25%). The SO₄²⁻ fraction was the only one with an annual mean for 2019 that was below -SD of the long-term mean. The sea salt aerosol fraction of PM₁₀ increased substantially (143%) at Birkenes in 2001 - 2019, partly due to an increased sea salt aerosol level, but also due to lower PM₁₀ levels. The NO₃⁻ fraction has also increased considerably (69%) for the period in question.

Based on levoglucosan measurements (Table 4.2) we estimate that biomass burning emissions contributed 5-9% to PM annually, considering both PM₁₀ and PM_{2.5}. The fraction attributed to biomass burning in winter was 11-21%, whereas it was ≤1.5% in summer, considering both size fractions. Spring

and fall are transition seasons with relative contributions lower than in winter and higher than in summer. Occasionally, high levels can be observed also in these seasons, such as in 2019, due to influence from agricultural and wild fires. Biomass burning occasionally exceeded 20% on a weekly basis for PM₁₀ and 30% for PM_{2.5} in the heating season, thus emissions are attributed to wood burning for residential heating. The very high contributions calculated for April are discussed in Chapter 7.

Table 5.3: Trends in aerosol particle species fractions of PM₁₀ and PM_{2.5} mass concentration using Mann-Kendall test and Sen slope estimates, significant level 0.05.

Site	Species/Fraction	Time period	Change (%)
Birkenes	SO ₄ ²⁻ to PM ₁₀	2001 – 2019	-34%
	NO ₃ ⁻ to PM ₁₀	2001 – 2019	69%
	NH ₄ ⁺ to PM ₁₀	2001 – 2019	not significant
	ΣNa ⁺ , Cl ⁻ , Mg ²⁺ to PM ₁₀	2001 – 2019	143%
	OC _{PM10} to PM ₁₀	2001 – 2019	Not significant
	EC _{PM10} to PM ₁₀	2001 – 2019	-25%
	TC _{PM10} to PM ₁₀	2001 – 2019	Not significant
	OC _{PM2.5} to PM _{2.5}	2001 – 2019	Not significant
	EC _{PM2.5} to PM _{2.5}	2001 – 2019	Not significant
	TC _{PM2.5} to PM _{2.5}	2001 – 2019	Not significant

Trends are calculated for time series extending 10 years

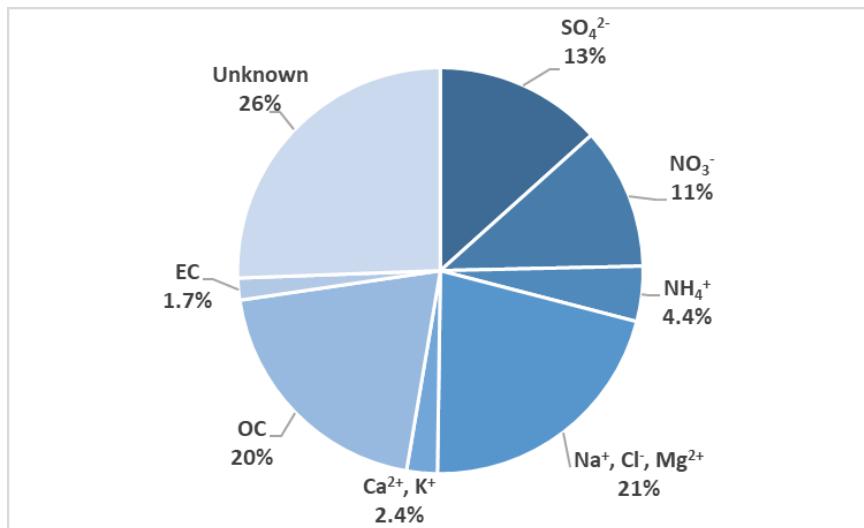

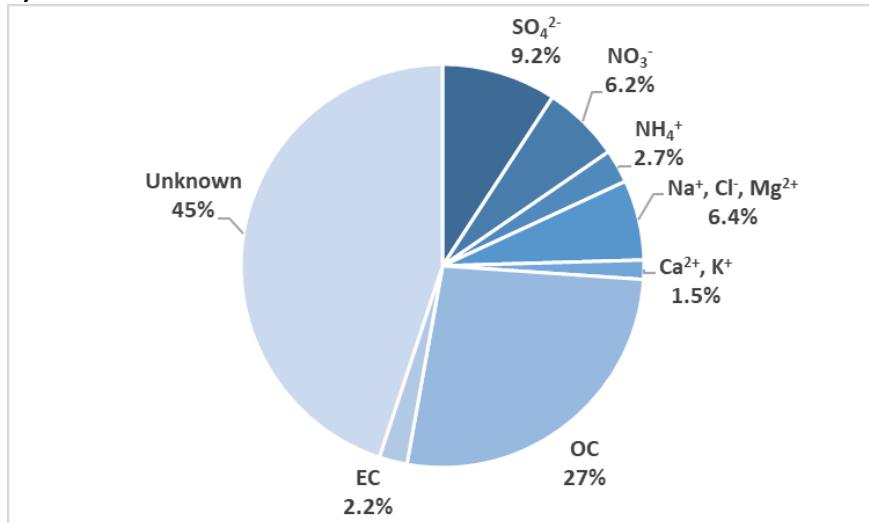

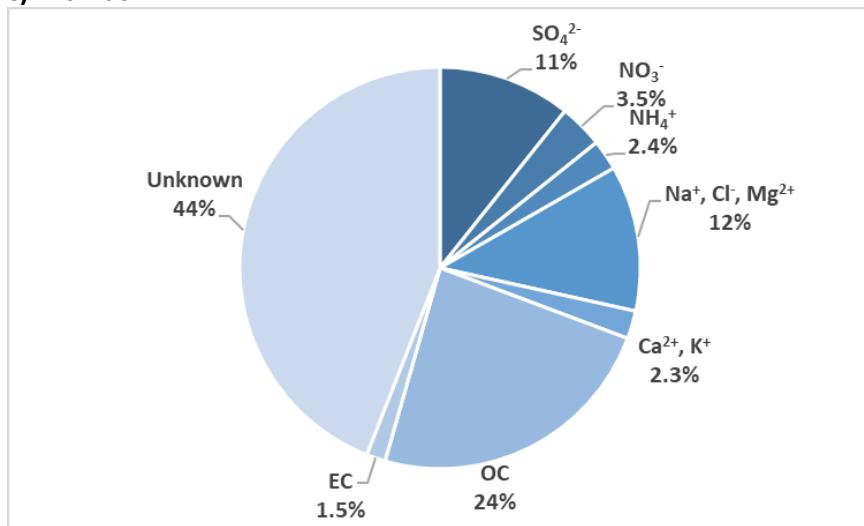

a) Birkenes**b) Hurdal****c) Kårvatn**

Figure 5.3 Annual mean chemical composition of PM_{10} at the Birkenes Observatory a), the Hurdal site b) and the Kårvatn site c) for 2019. The annual mean mass concentration for PM_{10} in 2019 was $4.6 \mu\text{g}/\text{m}^3$ at the Birkenes Observatory and at the Hurdal site and $2.9 \mu\text{g}/\text{m}^3$ at the Kårvatn site.

5.6 Particle number concentrations

The annual mean particle number concentration for the size range in particle diameter $0.01 < Dp < 10 \mu\text{m}$ (N_{Tot}) at Birkenes for 2019 was slightly lower (4%) than the long-term mean, but within one standard deviation of the long-term mean. The annual mean number concentration of the ultrafine particles N_{UF} ($0.01 < Dp < 0.1 \mu\text{m}$) (2% lower) and the accumulation mode particles N_{Acc} ($0.1 < Dp < 1.0 \mu\text{m}$) (9% lower) were lower than the long-term mean as well, which is to be expected as nuclei and Aitken mode particles, and to some extent the lower size fractions of the accumulation mode, dominate the particle number concentration. The annual mean N_{CM} ($1 - 10 \mu\text{m}$) size fraction could not be established for the entire year of 2019 due to problems with the optical particle counter. The missing N_{CM} data on have no detectable influence on determining N_{Tot} .

77% of N_{Tot} was attributed to N_{UF} and 23% to N_{Acc} at Birkenes for 2019, whereas the fraction associated with particles in the range $1.0 - 10 \mu\text{m}$, i.e. the coarse mode, could not be established. However, the fraction of particle number in the coarse mode is typically negligible at Birkenes. The fraction of N_{tot} attributed to N_{UF} and N_{Acc} do not vary much between years, whereas the variability is slightly higher for N_{CM} , due to low levels and thus larger uncertainty. N_{UF} was the dominating fraction regardless of season, accounting for 70 – 81% of N_{tot} . Typically, the N_{UF} fraction drops in winter, whereas the N_{Acc} fraction increases correspondingly, so also for 2019.

Table 5.4: Number concentrations for ultrafine, accumulation mode and coarse mode particles at Birkenes for 2010 – 2019 and their relative share to the total concentration. Unit: cm^{-3} .

Year $N (\text{cm}^{-3})$	Ultrafine particles ($Dp < 0.1 \mu\text{m}$)	(%)	Accumulation mode particles ($0.1 \mu\text{m} < Dp < 1.0 \mu\text{m}$)	(%)	Coarse mode particles ($1.0 \mu\text{m} < Dp < 10 \mu\text{m}$)	(%)	Total concentrations ($Dp = 0.01 - 10 \mu\text{m}$)
2010	973	73	362	27	0.256	0	1336
2011	1047	74	371	26	0.565	0	1418
2012	889	77	263	23	0.375	0	1152
2013	1020	77	304	23	0.391	0	1324
2014	1279	74	456	26	0.338	0	1735
2015	1326	77	390	23	0.340	0	1717
2016	1063	75	357	25	0.392	0	1421
2017	943	78	272	22	0.267	0	1216
2018	1151	72	444	28	--	--	1596
2019	1049	77	321	23	--	--	1370

5.7 Summary

Observed annual mean concentrations of PM_{10} and $\text{PM}_{2.5}$ in the Norwegian rural background environment are amongst the lowest in Europe (< $4.6 \mu\text{g}/\text{m}^3$). International and national limit values and air quality guidelines were not violated in 2019, neither on an annual nor on a 24-hours basis.

Organic matter (34 – 46%) was the major fraction of PM_{10} at all sites, followed by secondary inorganic aerosol (SIA) (17 – 29%) and sea salt aerosol (6 – 21%), whereas a 13% contribution of mineral dust was estimated at the Birkenes Observatory. The SIA and sea salt aerosol contribution was substantially higher at the southernmost site Birkenes due to the proximity to major anthropogenic emission regions in continental Europe and to the sea, respectively.

There was a significant downward trend for both PM_{10} and $\text{PM}_{2.5}$ (-34% - -45%) for the period 2000/01 – 2019, which is in line with emission reductions of primary and secondary sources in Europe. However, measurements of source specific compounds and high time-resolution measurements, along with transport modelling, are needed for a more detailed assessment of sources and source regions. Estimates based on levoglucosan measurements, suggest that biomass burning contributed 7-12% to PM annually, considering both PM_{10} and $\text{PM}_{2.5}$. The fraction attributed to biomass burning in winter was 11-21%, whereas it was < 2.5% in summer, considering both size fractions.

6 Ground-level ozone

Ozone in the troposphere originates from photo-chemical reactions in the atmosphere between volatile organic compounds (VOCs), carbon monoxide (CO), methane (CH_4) and nitrogen oxides (NOx) under the influence of solar radiation, as well as from the transport of stratospheric ozone into the troposphere. VOCs, CO and CH_4 are emitted from anthropogenic sources such as road and ship traffic, leakage of natural gas, use of solvents and chemicals etc., and NOx is mainly emitted from traffic and power plants. In addition, biogenic sources (trees and plants) contribute significantly to the emission of VOCs and CH_4 and to a smaller extent to NOx (microbiological activity in soils). On a global basis lightning is also an important source of NOx in the troposphere. Thus, tropospheric ozone is the result of what is produced by both natural and man-made processes. Furthermore, the weather conditions have a strong influence on the efficiency of the ozone formation since the chemical reactions are generally favoured by solar radiation and high temperatures.

Once formed, tropospheric ozone is only slowly degraded by chemical reactions with OH, HO_2 and NO₂. The chemical lifetime of ozone in the free troposphere is of the order of several weeks. At the land surface, however, dry deposition and uptake in vegetation are effective loss mechanisms for ozone. Ozone dry deposition is determined by the local topography and land use and could be very important for the concentrations observed at surface monitoring sites in summer, particularly at continental stations with a strong diurnal cycle in surface temperature. This influence will be most apparent during nights with stable atmospheric conditions while the daytime values will be less affected due to a deeper atmospheric mixing layer.

Ozone has negative impacts on health, vegetation and materials. According to European Environment Agency (EEA) particulate matter (PM) and surface ozone are Europe's most problematic pollutants in terms of harm to human health (EEA, 2014). Furthermore, surface ozone is considered to be the most damaging air pollutant to vegetation in Europe today, with significant effects on the growth of trees, on vegetation in general, and on important agricultural crops.

The health effects regard particularly asthmatics and people with chronic respiratory disorders. Effects on the vegetation regards particularly crops but also forests and natural vegetation. Prolonged exposure has shown negative impacts on forests. Materials such as rubber and other polymer compounds can also be damaged by ozone. As opposed to other pollutants, the baseline level of ozone, i.e. the concentration level in remote areas far from emission source regions, is fairly close to the threshold levels for effects on human health and vegetation. Thus, the environmental problems related to surface ozone is a regional and widespread phenomenon.

6.1 Monitoring network

Measurements of ozone has been going on in Norway since 1975, first in Telemark and from 1977 also around the Oslo fjord and in subsequent years extended to the whole country. EU's air quality directive (AQD) (EU, 2008: Directive 2008/50/EC) which is implemented in Norwegian legislation contains the thresholds and objectives regarding ozone levels and the requirements as to the number of monitoring sites. According to the directive, the country should be divided into a number of zones. The stations in the individual zones as of 2019 are indicated in the map in chapter 1 (Figure 1.1). The EU directive gives requirements for the minimum number of monitoring sites within each zone and for the country as a whole.

The ozone monitoring network in 2019 consisted of eight stations. Seven of these were operated by NILU, while the Porsgrunn municipality was operating the station at Haukenes. The station at Haukenes can be classified as suburban while the rest are rural background stations which implies that the sites are not affected by local emissions. The data from Haukenes were reported to the air quality database

at NILU where a final validation is done by the National Reference Laboratory for ambient air quality measurements.

Table 6.1 shows the monitoring sites and data capture for 2019, which was 94% or higher at all stations. The measuring method and principles are given in Annex 3.

Table 6.1: Ozone monitoring sites and data capture based on hourly values in 2019.

St.nr.	Station name	Period	Data capture
NO0043	Prestebakke	01.01.19 - 31.12.19	99%
NO0056	Hurdal	01.01.19 - 31.12.19	99%
NO0489	Haukenes	01.01.19 - 31.12.19	94%
NO0002	Birkenes II	01.01.19 - 31.12.19	99%
NO0052	Sandve	01.01.19 - 31.12.19	99%
NO0039	Kårvatn	01.01.19 - 31.12.19	99%
NO0015	Tustervatn	01.01.19 - 31.12.19	99%
NO0042	Zeppelin	01.01.19 - 31.12.19	99%

6.2 Ground-level ozone in Norway

In the scientific literature one often distinguishes between the “background” and the “baseline” level (e.g. Oltmans et al., 2013), in which the former refers to the pre-historic levels in an unpolluted atmosphere whereas the latter refers to the present levels in the northern hemisphere, far away from any emission areas.

The northern hemispheric ozone baseline level varies between 40 and 80 µg/m³ throughout the year and is typically highest in spring. On top of this baseline level, episodes with long-range transport of more polluted air masses increase the ozone levels regularly during the summer season. During winter the situation is the opposite, i.e. the transport of polluted air masses from the European continent leads to reduced ozone levels due to the titration reaction O₃ + NO → NO₂. This difference between winter and summer is explained by the intensity of the solar UV-radiation which leads to a fast photochemistry in summer and a corresponding slow and inefficient photochemistry in winter.

The ozone levels at a monitoring site is also influenced by local effects near the station such as dry deposition to the surface and episodes of local NOx emissions. In general, the Norwegian rural ozone stations are not much influenced by nearby emissions, but occasional short-term episodes of ozone degradation due to local NOx sources cannot be ruled out totally. These local effects will result in a reduction in ozone and thus an underestimation of the regional ozone exposure. Hence, in summary, the level of ozone is the net result of a hemispheric, a regional and a local component.

In Norway summertime episodes of elevated ozone are often associated with a high pressure located over the European continent, typically over Central or Eastern parts, setting up a southerly or southwesterly transport of warm, polluted air masses to the country. Ozone episodes are typically a fair-weather phenomenon associated with hot and sunny days. Furthermore, the highest ozone levels are often experienced just at the end of such fair-weather periods which is explained by an approaching cold front setting up an effective transport of photochemically processed air masses from the continent.

6.3 Norwegian ozone levels in 2019

Time series of daily maximum ozone values through 2019 are given in Figure 6.1 together with the climatological mean seasonal cycle (30 days running mean) based on previous years of data (2000-2018). The time series indicate a few marked episodes in 2019, most pronounced in the last part of April when more or less all stations show a marked peak lasting for many days. In addition, most stations show a less marked episode in late August and then a few sites (Prestebakke and Hurdal) show a short spike by the end of June.

The April episode was linked to transport of particularly warm air masses from south and southeast, and very likely extensive agricultural fires in East Europe contributed to the high ozone levels. Ineffective surface dry deposition of ozone in the Nordic countries this early in the season presumably also caused the ozone levels to remain high for many days. Peak ozone levels were recorded also in Sweden and Finland during late April and the episode is discussed in more detail in a separate chapter.

The smoothed seasonal cycles (14 days' running mean) in ground-level ozone in 2019 are shown in Figure 6.2 together with the climatological mean seasonal cycles for the period 2000-2018 for each site. The April episode is very distinct in this plot in particular for Prestebakke, Hurdal and Tustervatn.

In the summer season the ozone concentrations at many stations vary systematically over the day, particularly on days without strong winds. The concentration is low during stable night-time conditions, e.g. when inversions develop, and then rises quickly in the morning when the heating of the ground leads to the ozone rich air being mixed down. The highest levels are typically observed in the afternoon. This diurnal cycle is the result of ozone deposition to the ground combined with the daily cycle in vertical atmospheric exchange.

The mean diurnal cycle in ozone during April-September 2019 are shown for three selected sites in Figure 6.3. The strongest cycle is seen at Kårvatn, a valley inland station with a strong cycle in the height of the atmospheric mixed layer. A less pronounced ozone cycle is seen at Sandve, a coastal station where night-time inversions are less frequent. In contrast to this, the ozone values at the Zeppelin Mountain shows no diurnal cycle.

The diurnal cycle in ground-level ozone is a result of dry deposition to the surface combined with increased atmospheric stability during night-time. Since the deposition of ozone to water and ice/snow surfaces is very small and the monitoring site on the Zeppelin mountain is located above the planetary boundary layer there is no visible diurnal cycle in ozone at that site.

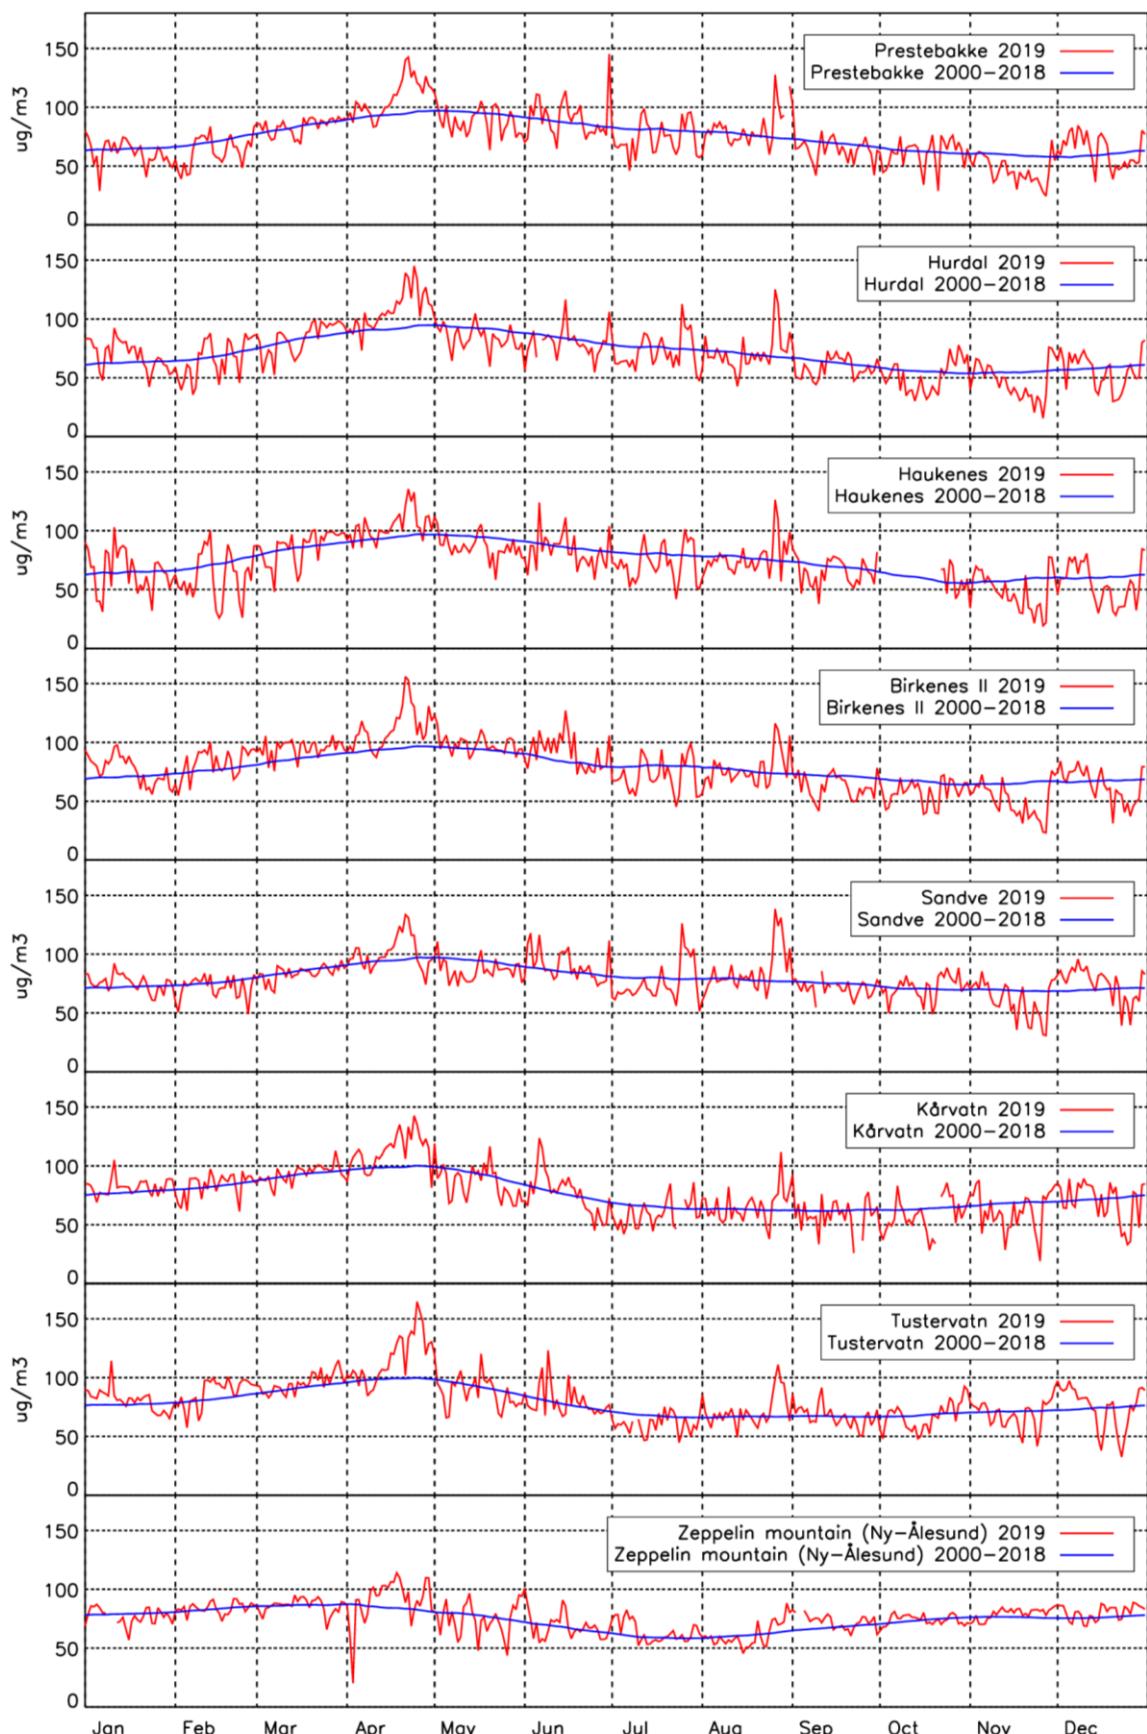

Figure 6.1: Daily maximum ozone concentrations in 2019 (red) together with the 30 days' running mean of the daily maxima for the years 2000–2018 (blue).

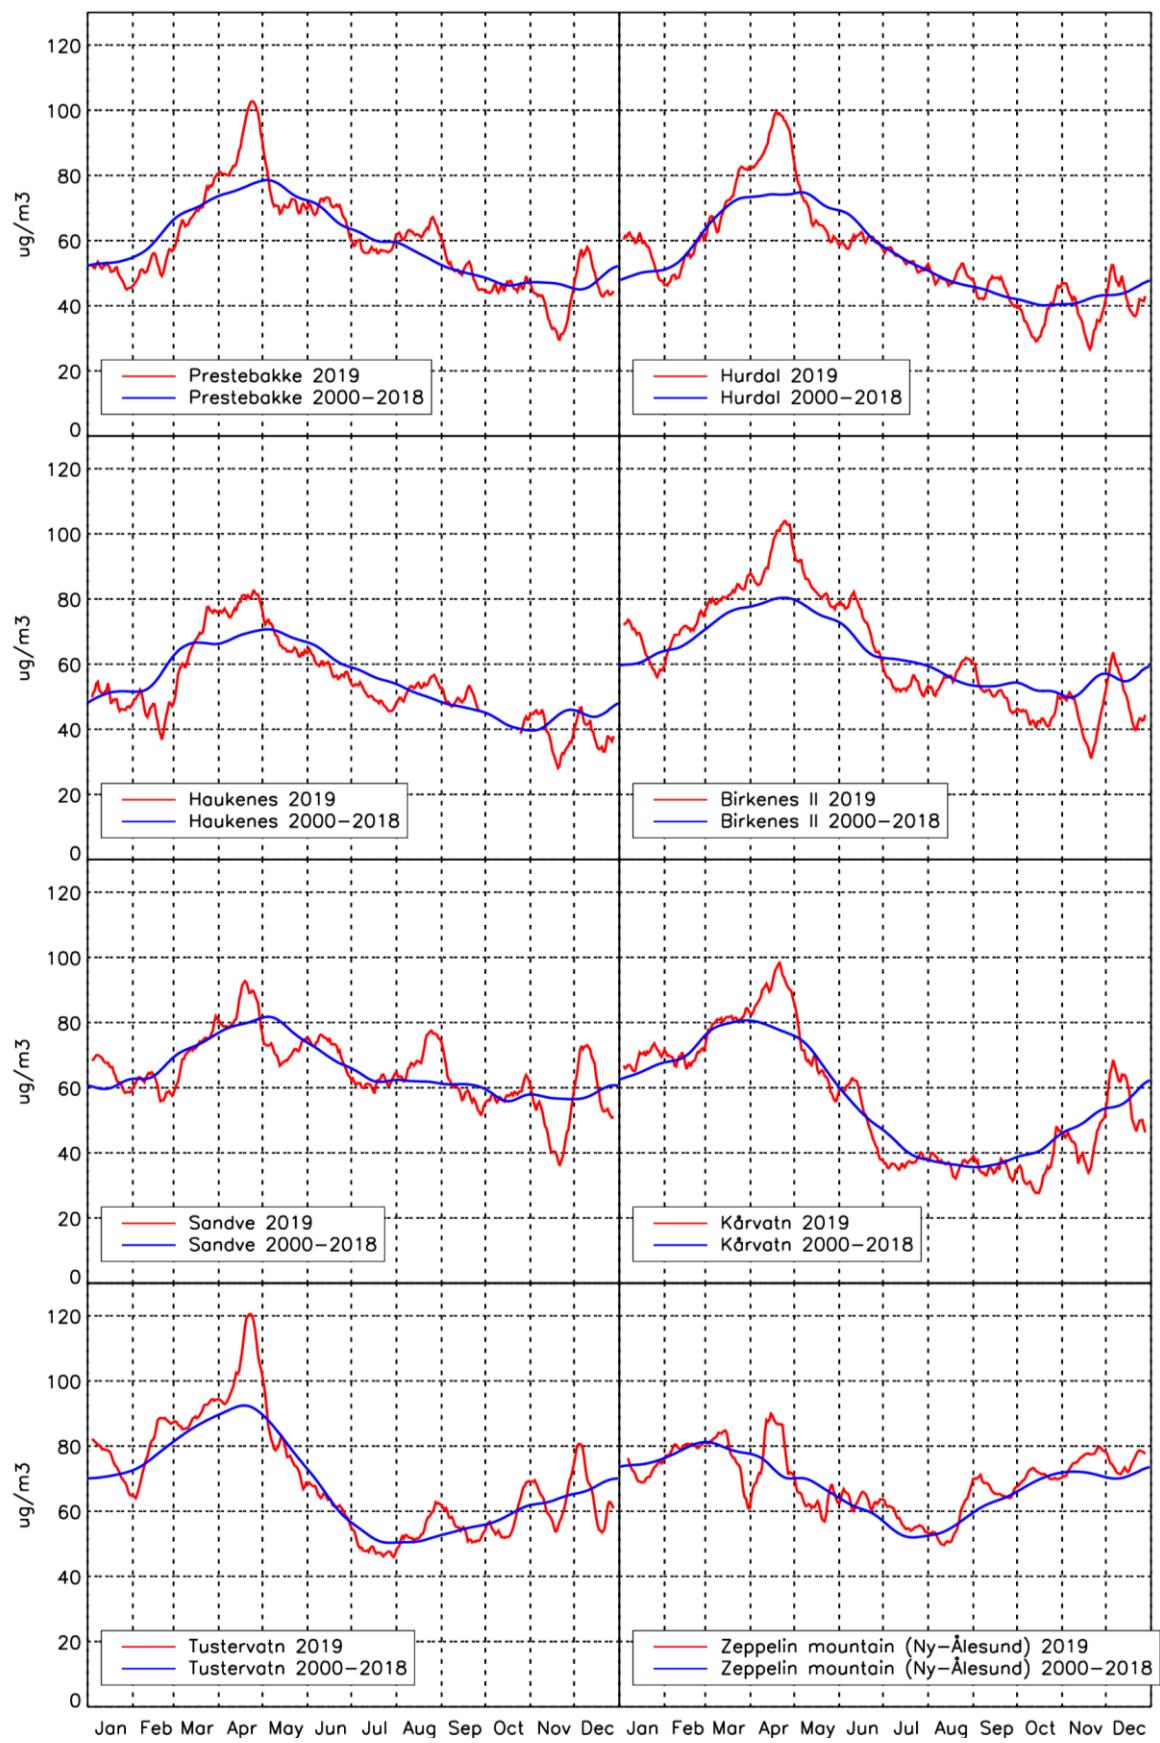

Figure 6.2: The 14 days' running mean ozone concentrations in 2019 (red) together with the corresponding mean concentrations based on all years 2000–2018 (blue).

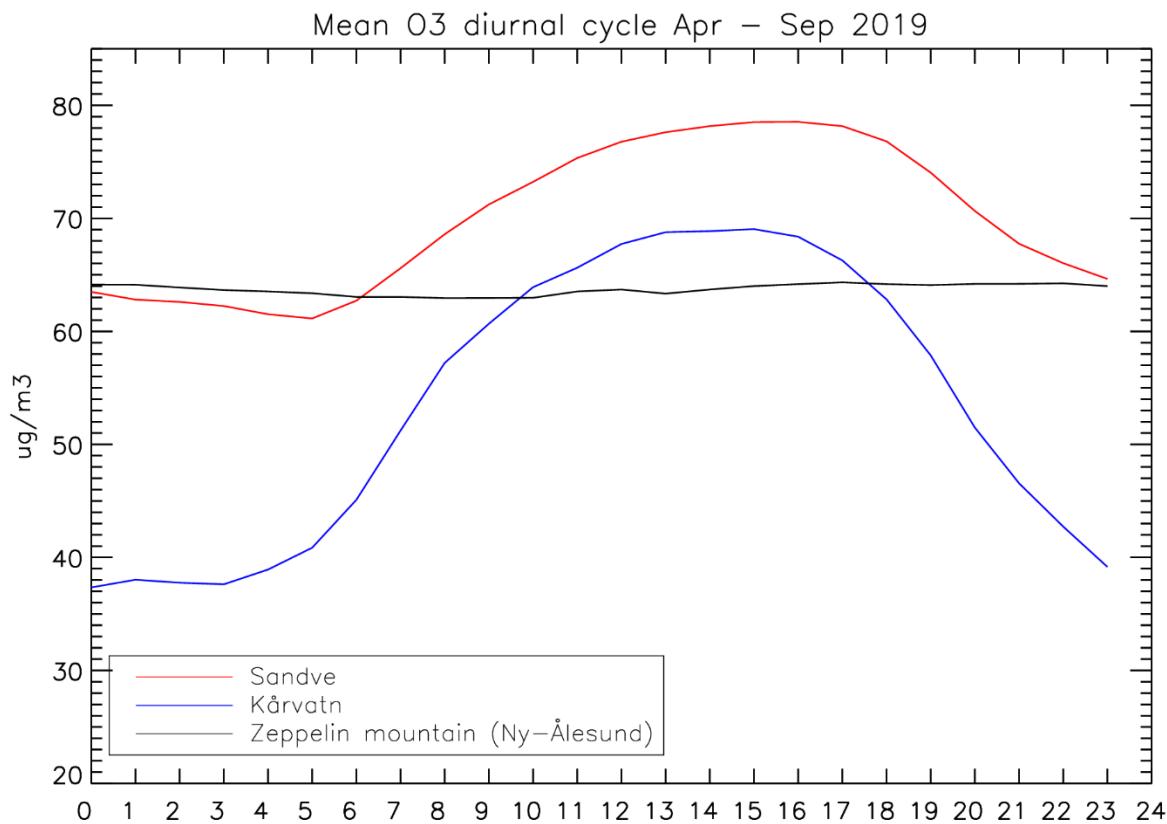

Figure 6.3: The mean diurnal cycle in ozone at three of the monitoring sites; Sandve, Kårvatn and Zeppelin Mountain during April-September 2019.

6.4 Exceedances of the limit values for protection of human health

Ground-level ozone can cause health problems, and the concentration level should not exceed certain limit values. Various air quality criteria for ozone for the protection of health are given in Table 6.2. EU's third daughter directive relating to ozone in ambient air was derived in 2002 (EU, 2002), and in 2008 a new air quality directive was adopted (EU, 2008). WHO has also defined certain air quality guidelines for ground-level ozone (WHO, 2006). Norway has implemented EU's air quality directive and information and warning bulletins are broadcasted to the public in case of exceedance of the information threshold ($180 \mu\text{g}/\text{m}^3$) and alert threshold ($240 \mu\text{g}/\text{m}^3$), respectively.

In 2013 a new set of national air quality guidelines were defined for ozone and other species. The national and the WHO guidelines as well as the EU directive values are given in Table 6.2.

Table 6.2: Limit values for ground-level ozone for the protection of human health.

Value ($\mu\text{g}/\text{m}^3$)	Averaging time (hours)	Ref	Description
180	1	EU (2008)	EU's information threshold
240	1	EU (2008)	EU's alert threshold
120	8 ¹⁾	EU (2008)	EU's target value. 8-hour mean value not to be exceeded on more than 25 days per year averaged over 3 years. To be fulfilled by 1.1.2010
120	8 ¹⁾	EU (2008)	EU's long-term objective.
100	8 ¹⁾	WHO (2006)	WHO's air quality guideline (global update 2005)
100	1	FHI (2013)	National air quality guideline (update 2013)
80	8 ¹	FHI (2013)	National air quality guideline (update 2013)

¹⁾ The highest 8-hour running mean value for each day calculated such that the 8-hour periods are assigned to the day on which the period ends.

The exceedances of the limit values for health are given in Table 6.3. The table shows the number of days with exceedance of WHO's air quality guideline of $100 \mu\text{g}/\text{m}^3$ and EU's long-term objective of $120 \mu\text{g}/\text{m}^3$. The number of hours with exceedance of EU's information threshold of $180 \mu\text{g}/\text{m}^3$ is also given as well as the annual hourly max value together with the date(s) that value occurred. The total number of hours with ozone data and days with at least 75% data capture through the year is given for reference. The exceedances based on the 8 hours mean values were only calculated for days with at least 75% data capture.

Table 6.3: For all sites in 2019 the number of hours with data and the number of days with at least 75% data capture together with the exceedances of health related air quality limits; national air quality guidelines, WHO guideline and EU's limit values as given in Table 6.2 as well as the annual maximum and the date when it occurred.

Station	Hours	National AQ guidelines		WHO		EU directive		Max. hourly value ($\mu\text{g}/\text{m}^3$)	Date
		Days	Days	Hours	Days	Hours	Days		
		>75%	8h > $80 \mu\text{g}/\text{m}^3$	1h > $100 \mu\text{g}/\text{m}^3$	8h > $100 \mu\text{g}/\text{m}^3$	8h > $120 \mu\text{g}/\text{m}^3$	1h > $180 \mu\text{g}/\text{m}^3$

Zeppelin	8644	364	126	151	10	0	0	114	18.04.2019

EU's information threshold (hourly value $> 180 \mu\text{g}/\text{m}^3$) has not been exceeded since 2006 and in 2019 the highest hourly ozone level was $165 \mu\text{g}/\text{m}^3$. It is remarkable that this peak level was recorded at Tustervatn in northern Norway, and the value is the second highest ozone concentration measured at this station since the monitoring started in 1989. Only during the strong ozone episode in 2006 (Stohl et al., 2007) higher ozone levels have been recorded at Tustervatn. The peak level in 2019 occurred during the April episode (25 April) and is likely a result of transport of warm air masses from southeast combined with extensive agricultural fires in East Europe.

EU's target value for the protection of human health are met in Norway with a very good margin. The long-term objective (=LTO, i.e. max 8h value $< 120 \mu\text{g}/\text{m}^3$) and thereby also WHO's and Norwegian

air quality guidelines is on the other hand exceeded to a variable extent every year. In 2019 the LTO was exceeded at all stations except Zeppelin Mountain. The highest number of days with exceedances was seen at Tustervatn with 13 days which is very unusual and is discussed in more detail in the mentioned chapter on the April episode.

The WHO guideline was broken at all sites (including Zeppelin Mountain) in 2019. This reflects that the WHO guideline level of $100 \mu\text{g}/\text{m}^3$ as an 8-hours mean is close to the baseline level, implying that a small change in the mean level will lead to a large change in the number of days with exceedances.

The ozone levels and exceedances vary strongly from year to year which is also indicated by Figure 6.4, showing the number of days with exceedance of the 8-hour mean value of $120 \mu\text{g}/\text{m}^3$ for the period 2000-2019. Table 6.4 gives the annual peak values and number of days with exceedance of the LTO from 2006 to 2019. The main reason for the inter-annual variations is variations in the large-scale weather conditions from one year to another. Over time, long-term changes in the European emissions of NOx and VOC as well as gradual trends in the hemispheric baseline level of ozone will be important.

Table 6.4: The annual maximum hourly ozone concentration and the number of days that EU's long-term objective was exceeded during 2006-2019 at one or more stations. Note that the monitoring network have changed over this period and thus the values are not directly comparable from year to year.

	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019

Number of dates with exceedance of EU's long-term objective of $120 \mu\text{g}/\text{m}^3$ a)	28	8	16	9	3	12	2	2	4	2	4	1	22	17

a) Running 8-h mean

The EU directive requires the countries to sustain monitoring stations in all air quality zones where the long-term objective has been broken in the last five years. As shown in Figure 6.4, this limit value has been exceeded at all stations the last five years. In 2019 the LTO was broken at 17 days which is the second highest number of dates since the peak year in 2006. As mentioned above, the highest number of exceedances was observed at Tustervatn (13 days).

The updated national guidelines (FHI, 2013) are even stricter than the WHO guideline (Table 6.2) and both the $80 \mu\text{g}/\text{m}^3$ (8-h mean) and $100 \mu\text{g}/\text{m}^3$ (1-h mean) were exceeded for long periods of the year in the whole country as shown by Table 6.3.

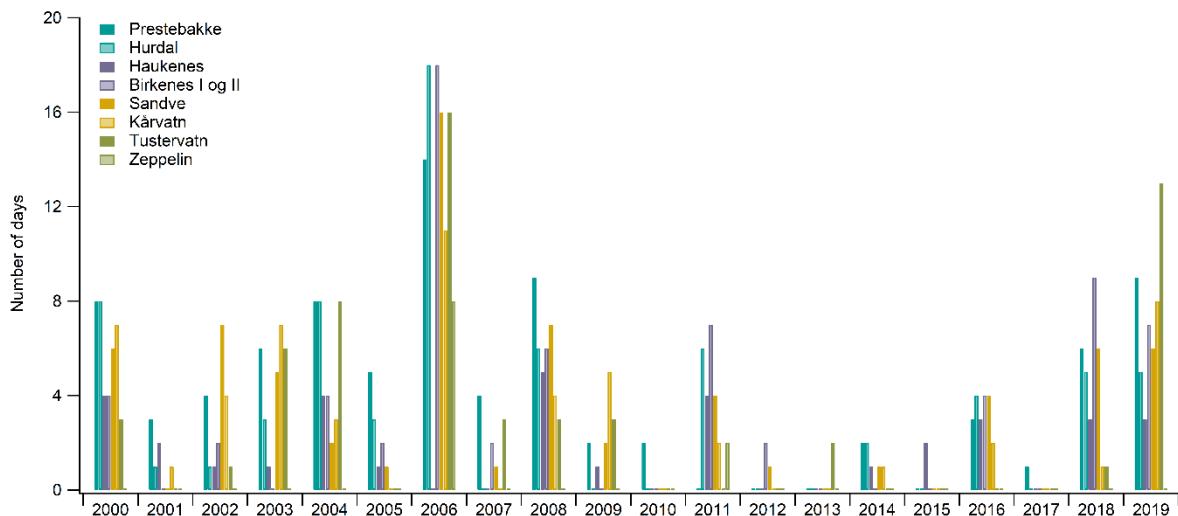

Figure 6.4: The number of days with a maximum daily 8-h mean ozone concentration above 120 µg/m³ for the period 2000-2019. Note that the Birkenes site has been moved, and data before 2010 refer to the old location. See text for more explanations.

6.5 Exceedance of the threshold values for protection of vegetation

Threshold levels for ozone exposure to vegetation has been set both by EU and UN-ECE. Within EU and to some extent within UN-ECE the limit values are based on the cumulative exposure over the threshold value of 40 ppb (= 80 µg/m³) and the parameter is termed AOT40 ("Accumulated exposure over the threshold of 40 ppb") as listed in Table 6.5. AOT40 is calculated as the sum of the differences between the hourly mean concentration and 40 ppb for each hour where the ozone concentration exceeds 40 ppb during a certain pre-defined growing season.

EU's air quality directive (EU, 2008) includes a target value (to be reached by 2010) and a long-term objective (without any deadline) for a 3-months AOT40 value relevant for semi-natural vegetation. UN-ECE (the Mapping Manual published by Mills et al., 2017) also provides 3-months critical levels for agricultural crops and semi-natural vegetation as well as a 6-months critical level for forests.

The procedure for calculating AOT40 differs, however, between the EU legislation and UN-ECE. According to the EU directive (EU, 2008) AOT40 should be based on the measured hourly ozone values from 08:00 – 20:00 CET (Central European Time) from 1 May – 31 July. UN-ECE on the other hand defines the hours with a global radiation > 50 W/m² to be included in the AOT calculation. Furthermore, UN-ECE defines growing seasons that vary with geographical location and altitude and, in addition, they require that the ozone values should be interpolated to the canopy height before calculating AOT40. When local meteorological measurements are not available, the Mapping Manual (Mills et al., 2017) includes tables for converting the measured ozone data to ozone levels at canopy height based on the land cover and surface data. Due to these complications, we use the much simpler 3-months AOT40 definition as stated in the EU directive in this report.

There is no critical level for 6-months AOT40 in the EU directive, and thus we use the UN-ECE definition for this although in a simplified way. For calculation of the 6-months AOT40 we use the measured data directly without any interpolation to canopy height. This is justified by the fact that the difference between ozone at the inlet height (typically 3-10 m above ground) and the typical canopy height for forests is small. Since the vertical gradient in ozone is largest near the surface, the main problem of interpolation is from the monitor's inlet height to the canopy height of smaller plants.

Table 6.5: Limit values for the protection of vegetation from ozone exposure.

AOT40 (ppb hours)	Period	Reference	Comment
3000	3-months growing season	Mills et al., 2017	UN-ECE's critical level for agricultural crops and semi-natural vegetation ¹⁾
5000	1 April – 30 Sept	Karlsson et al., 2003; 2005	UN-ECE's critical level for forests ¹⁾
9000	1 May – 31 July	EU, 2008	EU's target value for vegetation. Should be averaged over five years ²⁾
3000	1 May – 31 July	EU, 2008	EU's long-term objective for vegetation ²⁾

1) UN-ECE's AOT values should be based on the hours with global incoming radiation > 50 W/m²

2) EU's AOT values should be based on the period 08-20 CET and

3) EU's AOT values should be based on the period 08-20 CET

Research in recent years have shown that the AOT40 based critical levels for vegetation should be replaced with the so-called flux based critical levels (Mills et al., 2011) when assessing the actual impact on plants. The flux-based levels (named POD_y) takes into account various environmental conditions such as soil moisture, solar radiation, leaf area, vertical stability of the atmosphere, land cover etc, and thus provides a better estimate of the real ozone exposure of the plants. Comparison between AOT40 based levels and POD_y levels with ozone exposure experiments in the field have indeed confirmed that the flux approach is better suited for direct assessments of the actual effect from ozone on vegetation. Concentration based AOT40 values continue to be used, however, where the meteorological data and calculations from flux models are not available.

Table 6.5 shows the 3-months AOT40 values based on the definition in the EU directive (08:00-20:00 CET) for the period 1 May – 31 July 2018. Figure 6.5 shows the same 3-months AOT40 value for the years 2000-2019. EU's target value of 9000 ppb hours has not been exceed for many years in Norway. The long-term objective of 3000 ppb hours was exceeded only at Birkenes with 3557 ppb (corrected for data capture). This low number of exceedances of the critical level for vegetation reflects that the main ozone episode in 2019 occurred in April, before the defined 3-months period.

Table 6.6 shows the 6 months AOT40 values for forests (April-September) 2019 as based on the UN-ECE definition (using the hours with a global radiation > 50 W/m²), and the corresponding plot for the years 2001-2019 are shown in Table 6.6. The critical level of 5000 ppb hours for forests was exceeded at 4 of the 8 stations in 2019 (Prestebakke, Birkenes, Kårvatn and Tustervatn). The highest 6-months AOT40 value was seen at Birkenes with 6772 ppb hours.

Table 6.6: Data capture and 3-month's AOT40 values for vegetation for the period 1 May - 31 July 2019 (unit: ppb hours) according to the definitions in the EU directive.

Station	Data capture (%)	AOT40 (corrected for data capture)
Prestebakke	99	2153
Hurdal	99	1005
Haukenes	99	1253
Birkenes II	98	3557
Sandve	98	1509
Kårvatn	99	1245
Tustervatn	98	1358
Zeppelin	99	398

Table 6.7: Data capture and 6-month's AOT40 values for forests for the period 1 April – 30 September 2019 (unit: ppb hours) according to the definitions in UN-ECE's Mapping Manual.

Station	Data capture (%)	AOT40 (corrected for data capture)
Prestebakke	99	5226
Hurdal	100	3357
Haukenes	99	3488
Birkenes II	99	6772
Sandve	98	4253
Kårvatn	99	5135
Tustervatn	98	5712
Zeppelin	99	1589

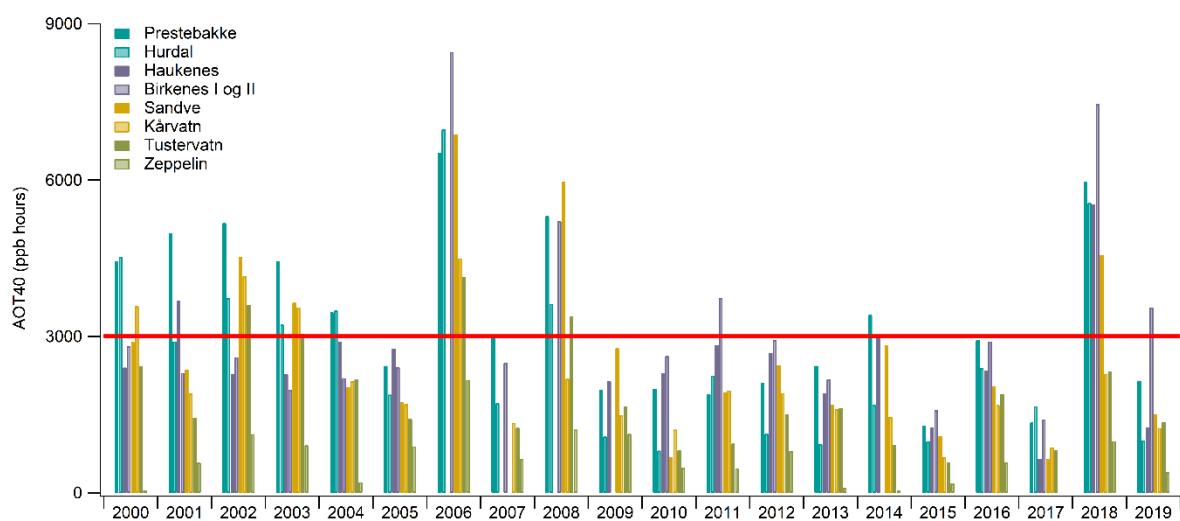

Figure 6.5: 3 months' AOT40 values (1 May - 31 July) for the years 2000 - 2019 (based on UN-ECE's definition of daylight hours). The EU directive's long-term objective of 3000 ppb hours is indicated by the line. Note that the Birkenes site has been moved, and data before 2010 refer to the old location. See text for more explanations.

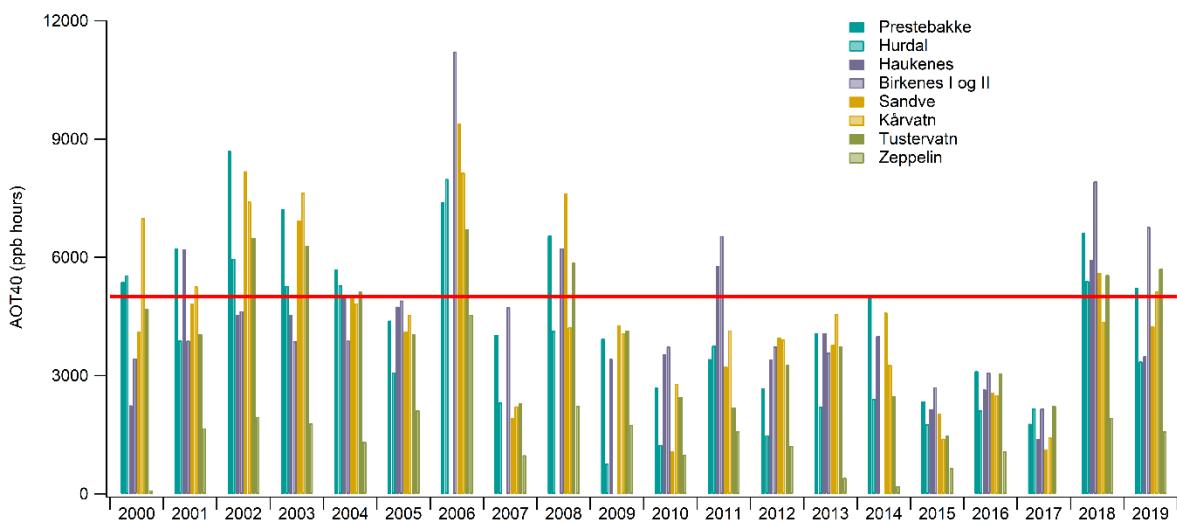

Figure 6.6: 6 months' AOT40 values (1 April - 30 September) for the years 2000 - 2019 (based on UN-ECE's definition of daylight hours, $> 50 \text{ W/m}^2$). The critical level for forests (5000 ppb hours) is indicated by the line. Note that the Birkenes site has been moved, and data before 2010 refer to the old location.

6.6 Long-term trends in ground level ozone

Owing to its long atmospheric lifetime the long-term trends of ground-level ozone in Norway are the net result of large-scale trends in the hemispheric baseline level with regional/European effects superimposed. Recent studies of the hemispheric baseline ozone indicate a doubling of the mean O_3 from the 1950s up to about the year 2000 followed by a decade with no growth or even reductions in O_3 at some sites, particularly in summer (Logan et al., 2012). Recent studies also indicate a change in the mean seasonal cycle of the baseline O_3 with the seasonal maximum being shifted from summer to spring in recent years. In contrast to the consistent picture for the baseline, the findings are more mixed for European monitoring stations. Tørseth et al. (2012) found strong declines in the highest O_3 values in the UK and Netherlands and no clear trends in Austria and Switzerland for the period 1990-2010.

Changes in monitoring network (both station locations and instrumentation/methods) is an obstacle to trend assessments. One needs consistent time series from stations running over multiple decades to detect surface ozone trends. A detailed inspection of the Norwegian monitoring history of ground-level ozone was carried out in 2003 (Solberg, 2003) which revealed many technical issues related to the monitoring procedures before 1997 when much more strict guidelines for the QA/QC work was put in operation. Before that year, a monitor in the field could be operating for years without calibration until it finally broke down and, additionally, the performance and stability of the ozone monitors were generally of poorer quality. The review in 2003 provided recommendations for selection of time periods with more reliable ozone for each station to be used for trend analyses. For simplicity we decided to base the trends only on the years from 1996 and onwards in the present chapter.

Figure 6.7 - Figure 6.9 show the development in three ozone metrics from 1990 to 2019; 3-months AOT40 (May-July), the number of days with an 8-h running max exceeding $100 \mu\text{g/m}^3$ (WHO guideline) and the 97-percentile of the daily max 8-h running mean April-September. The latter metric corresponds approximately to the annual 4th highest value used in the ozone trend assessment within the EMEP TFMM (Colette et al., 2016) and IGAC TOAR (Tropospheric ozone assessment research) programmes.

Results for four stations with long-term monitoring history are given: Prestebakke, Sandve, Kårvatn and Tustervatn. The values for all years are shown, however only the data from 1996 and onwards were included in the Mann-Kendall/Sen's slope trend estimate. Furthermore, the data from 1998 from Prestebakke were excluded from the analyses based on the mentioned evaluation of the monitoring history (see Solberg, 2003 for details). The trend lines are only given when a statistically significant ($p=0.05$) trend is found.

Downward levels are calculated for the 3-months AOT40 at all four sites, but the trend is statistically significant ($p=0.05$) only for Kårvatn with a reduction corresponding to 2.72%/year relative to 1995 as a start year.

In contrast, the number of days with a maximum 8-h concentration exceeding 100 $\mu\text{g}/\text{m}^3$ shows a significant reduction at three sites (Sandve, Kårvatn and Tustervatn, but not Prestebakke), and the 97-percentile of the daily max 8-h concentration shows a significant reduction at Prestebakke and Kårvatn.

A reduction in high ozone concentrations are expected due to the substantial reduction in European man-made emissions of NOx and VOC the last decades. The analyses shown here are in line with this. The selection of ozone metric, time period, station and the monitoring procedures are, however, crucial for the estimated trend values. Within the IGAC initiative TOAR a very long list of various ozone metrics is presently used for global trend assessments. Whereas trends in ozone guideline metrics (AOT, exceedance of limit values etc.) are the main interest of the effect community, these metrics are not necessarily the metrics most relevant for evaluating the effect of man-made emission abatement.

Furthermore, observational trends are the combined result of the influence from inter-annual meteorological variability and changes in man-made emissions of ozone precursors. Only supporting modelling data could indicate the influence of each of these effects separately.

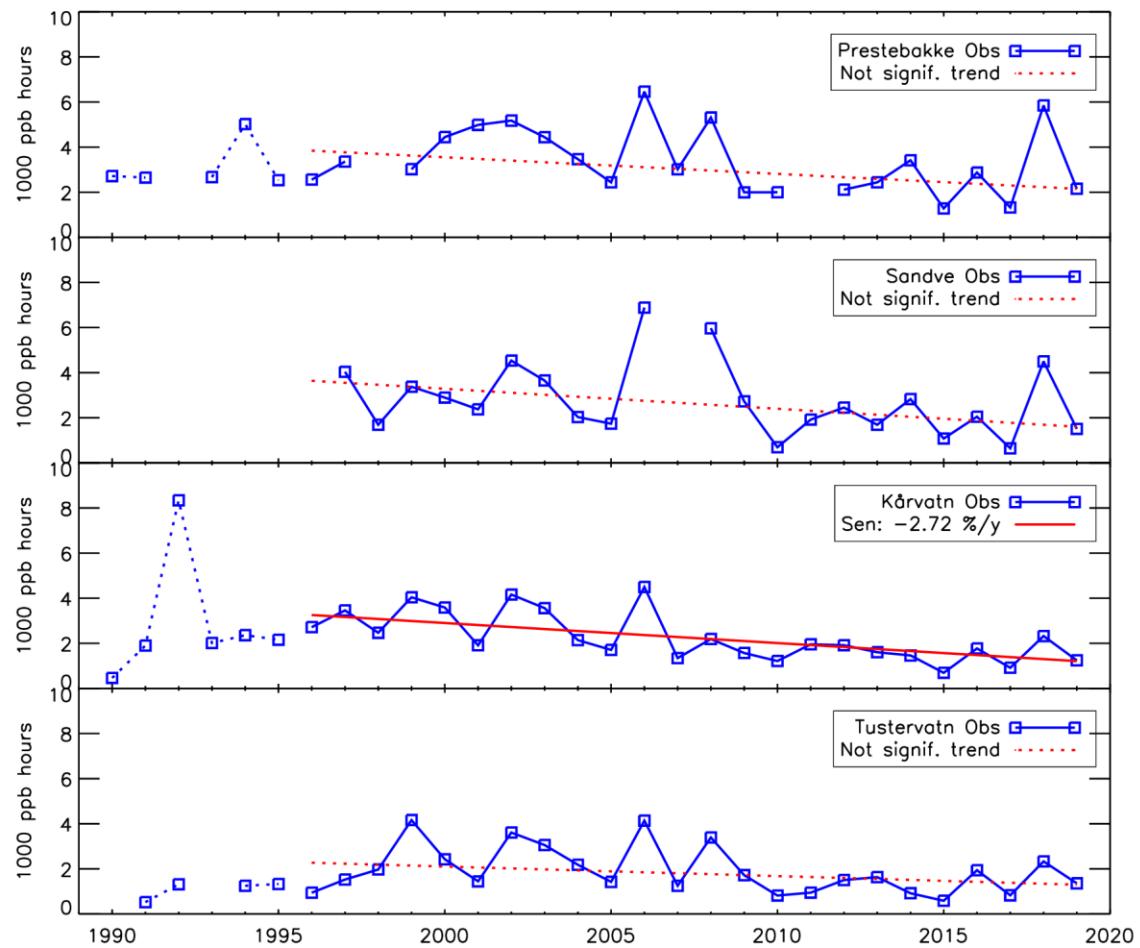

Figure 6.7: The 3-months AOT40 value according to the EU directive (May - July, hours 8-20 CET) during 1990-2019 for four sites. The estimated Sen's slope based on annual data for 1996-2018 are marked in red. Data from the first years (1990-1995) are uncertain and not included in the trend calculations and marked with a dotted line. Note also that all data from Prestebakke in 1998 were not used due to data quality concerns. The percentage trend value refers to 1995 as the start year.

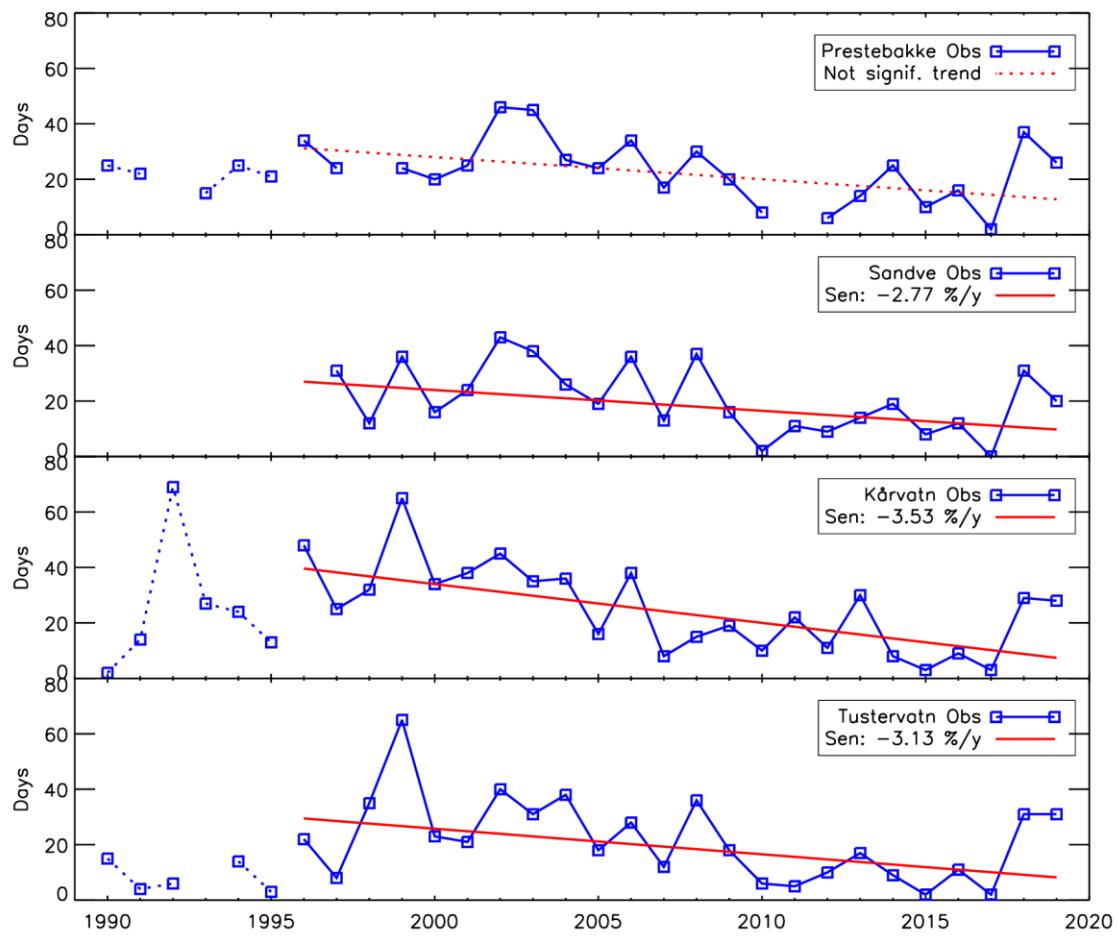

Figure 6.8: Same as Figure 6.7 for the number of days with a maximum 8-h running mean ozone concentration exceeding $100 \mu\text{g}/\text{m}^3$ (WHO guideline).

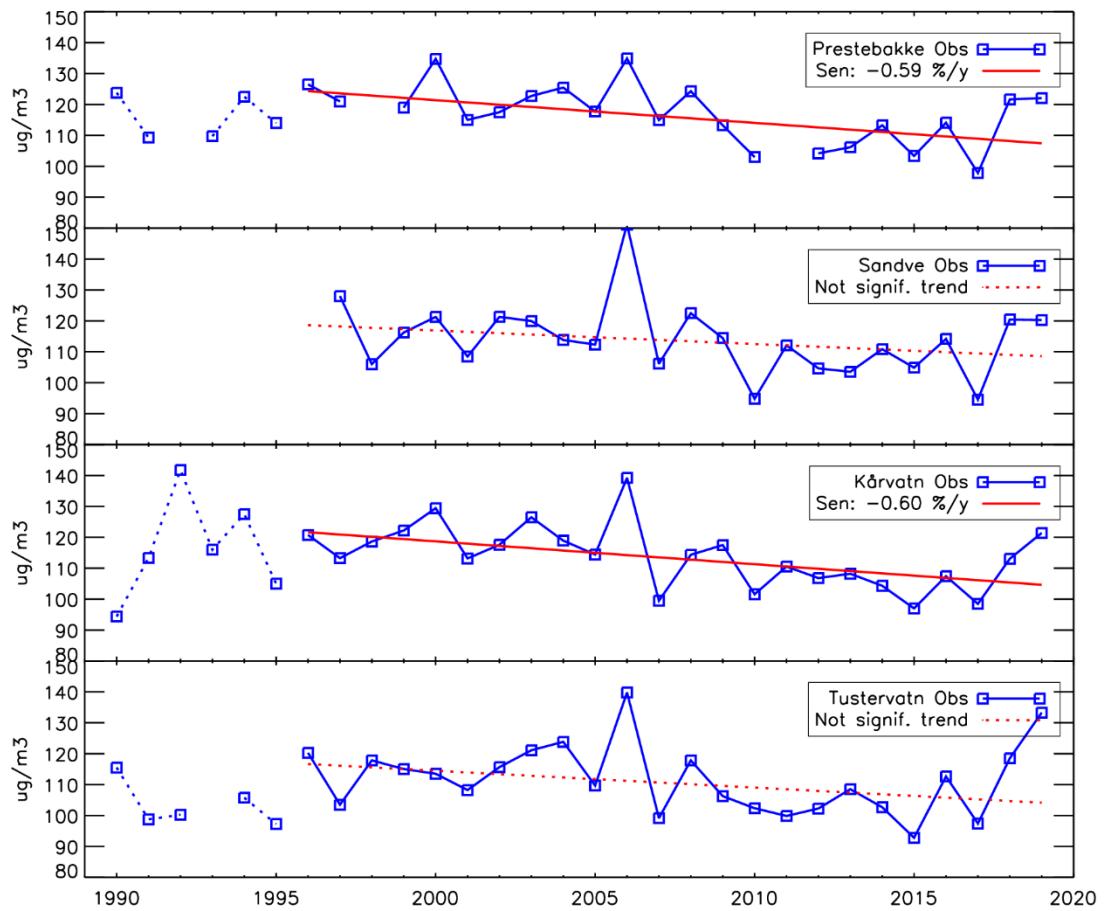

Figure 6.9: Same as Figure 6.7 for the 97-percentile of the daily maximum 8-h running mean ozone concentration April-September.

6.7 Summary

The surface ozone levels in Norway 2019 were characterized by one very marked and long-lasting episode in April as well as shorter episodes in August and late June. The critical level for vegetation linked to 3-months AOT40 for plants covering the period May-July was thus exceeded only at Birkenes whereas the 6-months AOT40 for forest covering April-September were exceeded at four sites. The highest hourly ozone concentration in 2019 was measured at Tustervatn ($165 \mu\text{g}/\text{m}^3$) and the highest number of exceedances of EU's long-term objective of max 8-hours daily max of $120 \mu\text{g}/\text{m}^3$ (13 days) was also seen at this station. This is remarkable as the ozone levels normally is higher in the southern part of the country. The reason behind the high ozone levels in the north was a long-lasting episode in April linked to transport of warm air masses from south and southeast. Emission from extensive agricultural fires in East Europe combined with ineffective surface dry deposition of ozone likely contributed to the higher levels of ozone.

In Norway, the levels of ground level ozone are determined by a baseline-level varying between $50-100 \mu\text{g}/\text{m}^3$ (minimum in autumn, maximum in late spring) with a number of summertime photochemical ozone episodes superimposed on this baseline. The baseline does not change that much from year to year, but the photochemical episodes vary substantially between years depending on the summer weather conditions and the European emissions. Whereas the summer weather conditions vary considerably from one year to another, the European precursor emissions have been steadily reduced over the last 20 years. Thus, a gradual decline in ozone episodes are expected in Norway although a certain amount of "noise" in the time series is expected due to the variation in the weather conditions, and to some extent this noise could mask the effect of the emission reductions.

7 The April 2019 episode

7.1 Meteorology and ground level ozone

April 2019 was the second warmest and second driest April in Norway since 1900. Areas in the far north and at the west coast experienced a monthly mean temperature 4–5°C above the normal, and many sites in the southeast had only 25 % of the normal precipitation. Particularly high temperatures were seen in the last part of the month, peaking at 25°C at Nesbyen 29 April. Associated with these weather extremes, high levels of several pollutants were observed.

The reason for these extremes was a persistent high-pressure system. At the start of the month an extensive high-pressure area was located over the northeastern part of the Eurasian continent. In the following days it moved slowly and was centered over mid-Norway in the middle of April. Gradually, the high-pressure area was displaced southeastwards setting up southerly and southeasterly winds to the Nordic countries as seen by Figure 7.1.

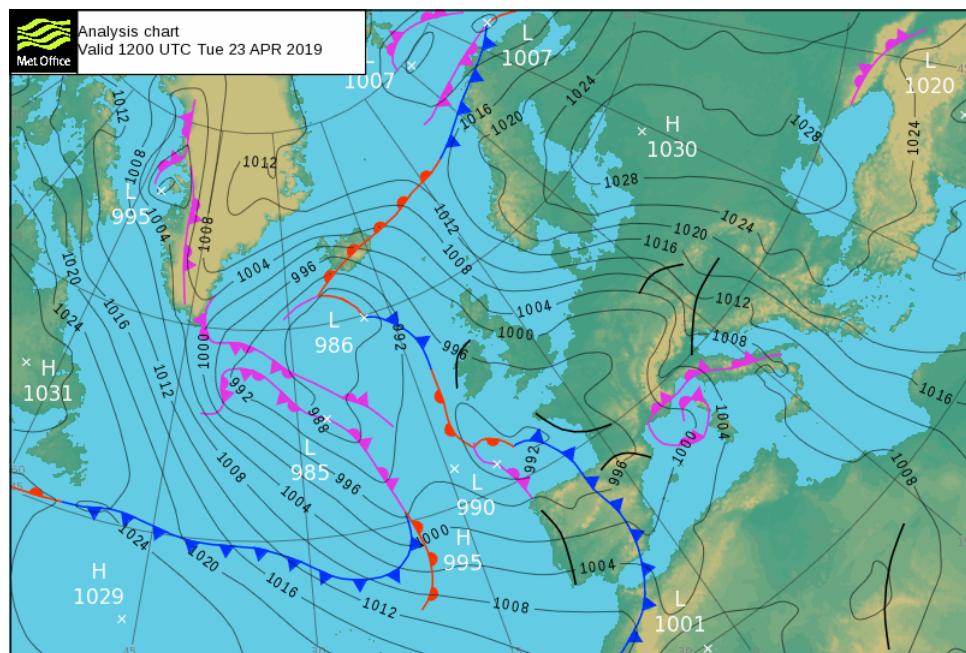

Figure 7.1: Surface pressure chart for 23 April 2019 12 UTC showing the high-pressure region in the east and low-pressure over the Atlantic setting up south-southeasterly flow into the Nordic countries. (Used with permission by © British Crown copyright, Met Office <http://www.metoffice.gov.uk/about-us/legal/tandc#Use-of-Crown-Copyright> <http://www.nationalarchives.gov.uk/doc/open-government-licence/version/3>)

This type of weather pattern is called a blocking high, implying that it blocks all the fronts and low-pressure systems than normally travels from west to east into Scandinavia. The blocking high will deflect the jet stream that determines the path of the low-pressure systems and cause the lows to travel either northwards over the ocean to the Arctic or southwards towards the Mediterranean. When the high-pressure system is located southeast of the Nordic countries as in the last part of April 2019, southerly winds will typically carry warm and dry continental air masses to Scandinavia.

This weather situation is often associated with elevated levels of pollutants in Norway for several reasons: Firstly, the air masses entering the country could have a long residence time over the European continent, meaning that surface emissions are accumulated in the air masses for many days. Secondly, the high-pressure region is associated with stable air masses without efficient vertical mixing. This means that the emissions that are accumulated in the air masses on the way to the Nordic

countries will be trapped in a shallow surface layer. Thirdly, high temperatures as seen in these situations is likely to cause the formation of ozone and secondary aerosol particles. Finally, the dry deposition of ozone, which normally is the main loss mechanism of this pollutant will be reduced in these situations due to drought causing the vegetation to close their stomata. The dry conditions also imply reduced wet removal of aerosols. In the April 2019 episode large areas in the Nordic region was still snow-covered, thus both the ozone uptake in vegetation and the dry deposition to the surface was likely very inefficient.

The meteorological conditions described favoured the accumulation of pollutants in the air masses that affected the Nordic countries. However, other important factors likely contributed to the high pollutant levels observed. On the 24 April, met.no announced that air masses carrying Saharan dust would cover large parts of the country the next days, a phenomenon clearly visible from satellites. Indeed, outflow of mineral dust from the African continent can be seen over the Mediterranean Ocean south of Sicily in.

Equally important (or maybe more important) was extensive fires in Eastern Europe, including Ukraine and western Russia. Figure 7.1 shows a picture from the MODIS satellite identifying fires by their infrared (heat) radiation. Numerous fires are seen over a large area upwind of the Nordic countries. A narrow plume of hazy air masses is seen entering southern Sweden. These fires are most likely agricultural fires used to burn farmland in early springtime in this region.

Backward trajectory calculations with the Flexpart model (Stohl et al., 2005; Pisso et al., 2019) can be used to identify the surface source region for the pollutants measured at the Norwegian monitoring stations, or the so-called footprint emission sensitivity. Examples of this are shown in Figure 7.3 for air masses arriving at Tustervatn 24 and 25 April, respectively. These maps indicate a close agreement between the wildfires and the source region for the air masses arriving at Tustervatn these days.

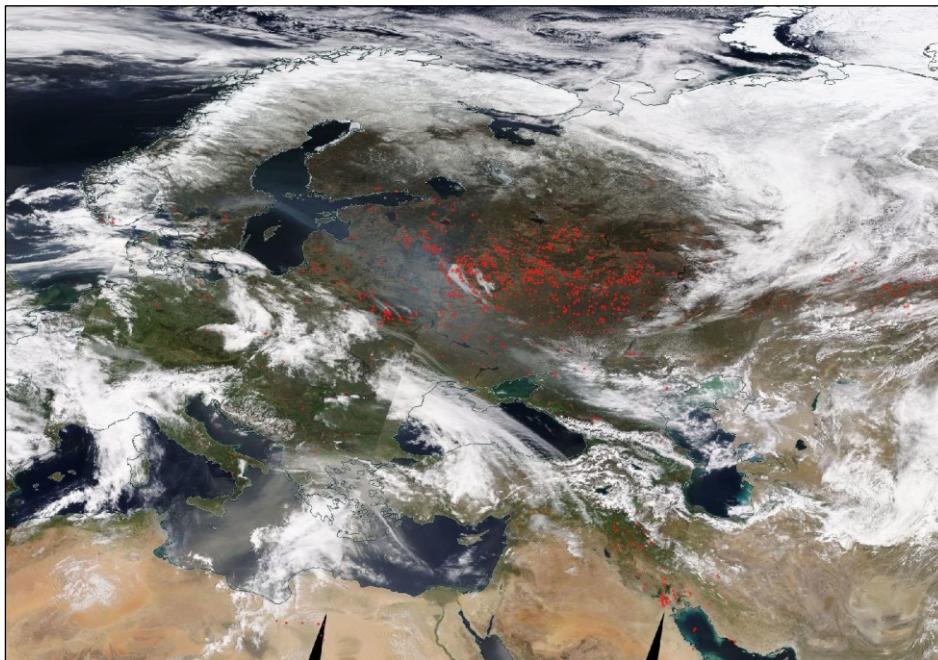

Figure 7.2: MODIS satellite picture from 24 April 2019 with wildfires marked as red dots on the map. A tongue of hazy air masses is stretching from the fire areas into southern Sweden (acknowledgement: <https://lance-modis.eosdis.nasa.gov/>).

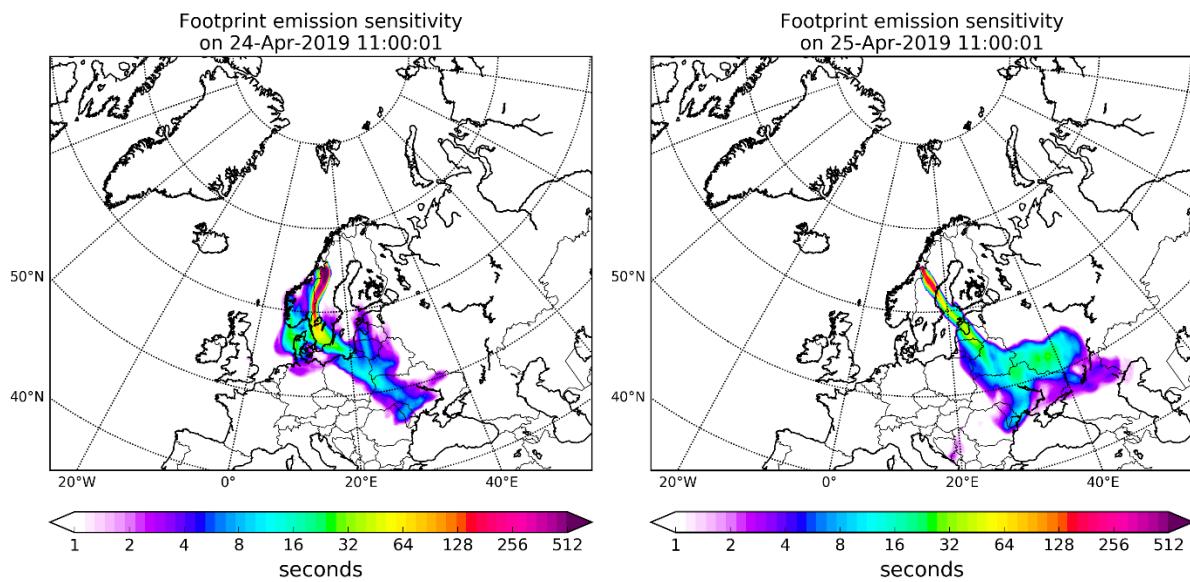

Figure 7.3: Footprint emission sensitivities calculated with the Flexpart model (Pisso et al., 2019) for the Tustervatn site.

Figure 7.4 shows the hourly ozone concentrations measured at three of the national monitoring stations (Kårvatn, Hurdal and Tustervatn) for the period 10 April to 10 May 2019. These time series show the build-up of the episode where the daily maximum levels are very close at these three sites. Then, during several days (25 - 28 April) the ozone level at Tustervatn stays particularly high and significantly higher than the other sites. This period matches the period with transport from the wildfire regions (Figure 7.3) and thus it is likely that emission from these fires lead to ozone formation that added on to the already high levels of ozone.

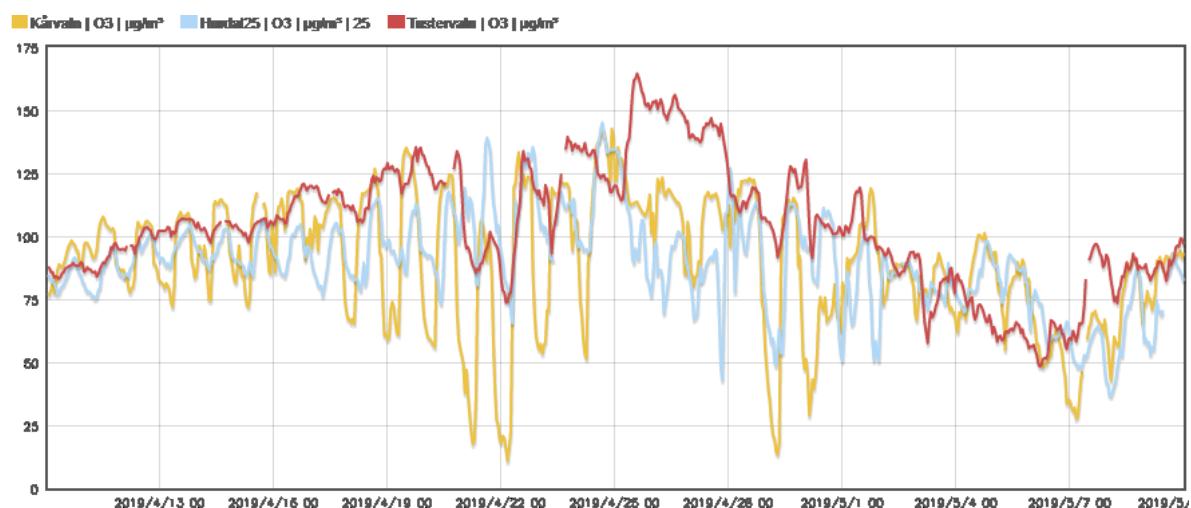

Figure 7.4: Hourly ozone concentrations ($\mu\text{g}/\text{m}^3$) at Kårvatn, Hurdal and Tustervatn during the period 10 April - 10 May 2019.

7.2 PM variables

Particulate matter was elevated for large parts of April at Birkenes, Hurdal and Kårvatn, and particularly in the first (3 – 10 April) and the last week (24 April – 1 May) of the month, differing from O_3 , which was elevated only in the last part of April. The weekly mean PM_{10} concentration was higher in the last week ($15.9 - 19.6 \mu\text{g m}^{-3}$) of April compared to the first one ($7.5 - 12.7 \mu\text{g m}^{-3}$) but both were

dominated by the fine fraction ($\text{PM}_{2.5}$) (60 – 70%). Hourly concentrations of $\text{PM}_{0.8}$ calculated from the particle counter measurements at Birkenes exceeded $30 \mu\text{g m}^{-3}$ for the period considered, whereas the maximum 24-hour mean was $26.4 \mu\text{g m}^{-3}$. Considering all of April, 11 days experienced $\text{PM}_{0.8}$ concentrations higher than $15 \mu\text{g m}^{-3}$, all of them associated with the two episodes in question, thus violating the National Air Quality Guideline for $\text{PM}_{2.5}$. Our calculations also indicate that the WHO Air-Quality Guidelines for $\text{PM}_{2.5}$ was violated, as the 99th percentile of $\text{PM}_{0.8}$ for 2019 was $25.7 \mu\text{g m}^{-3}$.

The episode affected large parts of southern Norway, thus also the air pollution level in urban areas. PM levels observed in Oslo were clearly enhanced, particularly for $\text{PM}_{2.5}$, which is less influenced than PM_{10} by resuspended road dust of local origin peaking at this time of the year

(www.luftkvalitet.info). The $\text{PM}_{2.5}$ levels observed at Birkenes and Hurdal at the two actual weeks in April amounted to 60% of that observed at urban background sites in Oslo.

The more extensive suit of aerosol particle measurements at Birkenes compared to Hurdal and Kårvatn allows for a verification of the aerosol particle sources indicated by the combination of FLEXPART footprints and satellite images (c shows that the mineral dust species Al, Fe and Ti were elevated for all of April, particularly for the two periods in question. A mineral dust concentration of $3.1 \mu\text{g m}^{-3}$ was calculated for April, which was 5 times higher than the estimated annual mean ($0.6 \mu\text{g m}^{-3}$). Mineral dust made a 28% contribution to PM_{10} in April, which was comparable to that seen for the two episodes (24 – 27%), although a higher mineral dust concentration ($4.1 \mu\text{g m}^{-3}$) was calculated for the last week. In addition to the agricultural fires in Western Russia, Belarus and the Ukraine clearly visible in the satellite images (Figure 7.5), outflow of mineral dust from the African continent can be seen over the Mediterranean Ocean south of Sicily in the bottom right image, which the FLEXPART footprint nicely links to the elevated levels of mineral dust at Birkenes for the last week of April. The footprint for the first week of April does not include the African continent, not even for the preceding 30 days, hence the mineral dust has a different origin. Except from Northern Africa and the Eastern Mediterranean the two footprints are remarkable similar, covering the Balkans and Eastern Europe. A vast part of this region is arable land subject to agricultural activity, which could be a possible source, as can wind-blown dust from semi-arid and dry areas governed by favorable meteorological conditions, but this remains speculative. There are only minor differences in the mineral dust composition at Birkenes for all of April, which could indicate that most of the mineral dust has a common origin. A 30 – 40% contribution of coarse aerosol particles as indicated in Figure 7.5Figure 7.6 panel a match well with a profound mineral dust contribution of nearly 30% for April, as mineral dust mainly resides in the coarse fraction of PM_{10} .

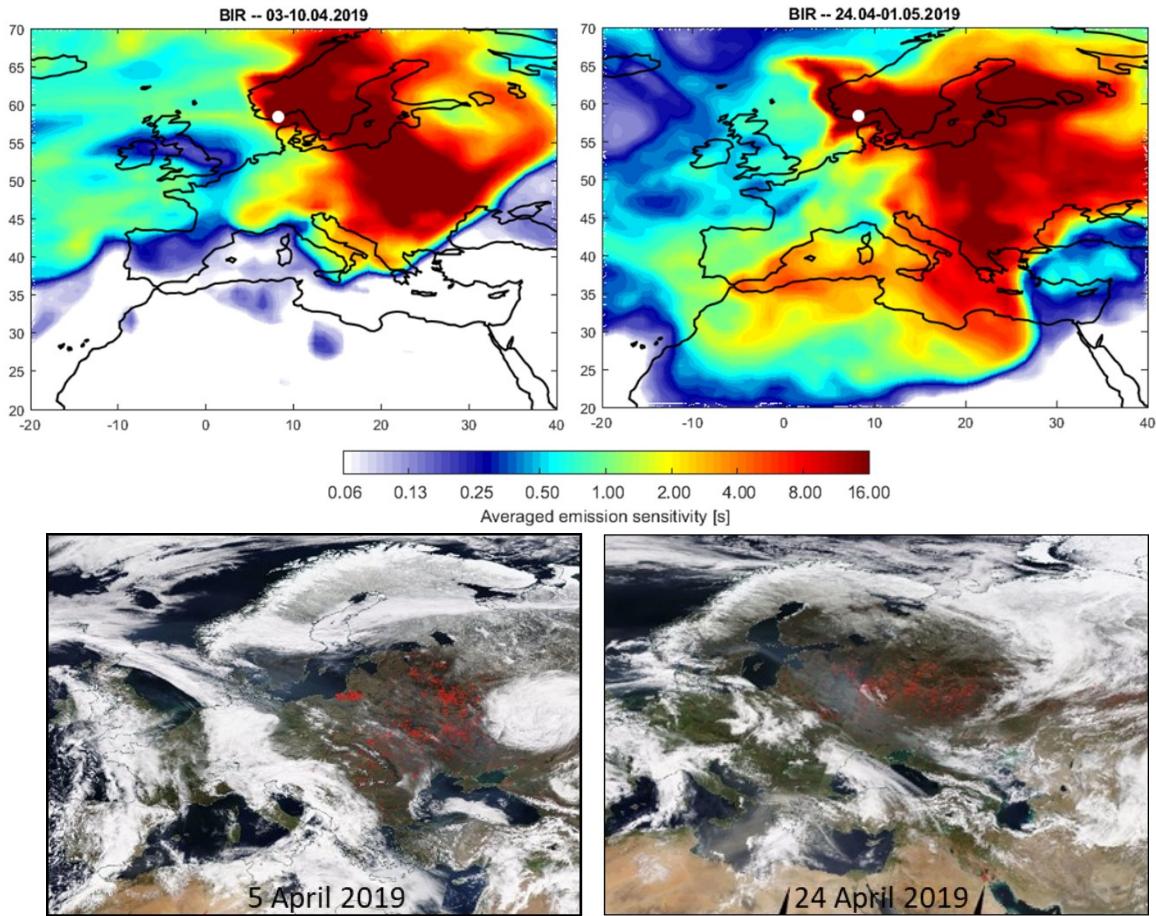

Figure 7.5: Footprint emission sensitivities calculated using the Flexpart model (Pisso et al., 2019) for the periods 3–10 April (top left) and 24 April – 1 May (top right) at the Birkenes Observatory and MODIS satellite picture from 5 April (bottom left) and 24 April 2019 (bottom right) with wildfires marked as red dots on the maps.

As for the mineral dust elements, the highest levels of OC and EC were seen for the two episodes in April (Figure 7.6 , panel d and f). Indeed, the weekly mean concentrations for OC in PM_{10} are the second ($4.4 \mu\text{g C m}^{-3}$) and third ($4.0 \mu\text{g C m}^{-3}$) highest reported since measurements started in 2001, whereas for $\text{PM}_{2.5}$ it was the 5th and the 10th highest. This is in line with previous findings, showing that the highest values of OC observed at Birkenes are associated with emissions from major agricultural- and wild-fires in Eastern Europe, hundreds of kilometers away (Yttri et al., 2007; Yttri et al., in prep.).

Highly elevated levels of the biomass burning tracer levoglucosan were seen for both weeks (Figure 7.6 panel e). Levoglucosan alone cannot be used to differentiate between emissions from residential wood burning and wild and agricultural fires for transient periods (spring and fall). However combining the FLEXPART footprints, the MODIS satellite pictures and the levoglucosan measurements clearly point to agricultural fires in Western Russia and Belarus for both episodes (Figure 7.5). We have used emission ratios reported by Yttri et al. (2014) to provide an estimate of the contribution of these fires to the observed PM level. We emphasize that these are crude estimates only, as for the estimates made for mineral dust. We find that the contribution from the fires to PM_{10} was twice as high for the first week ($33 \pm 6\%$) compared to the second week ($17 \pm 3\%$).

A noticeable part of OC (18 – 34%) was present in the coarse fraction of PM₁₀, particularly in the first week. There can be several explanations to this, including primary biological aerosol particles (PBAP) and carbonate (CO₃²⁻) carbon from mineral dust, which predominantly reside in the coarse fraction. Further, raging fires can cause a strong pyroconvection that effectively facilitates entrainment of coarse particles to high altitudes, enabling them to atmospheric transport over long distances.

Work in progress (Yttri et al., in prep.) suggests that climatological and meteorological conditions that favor transport of mineral dust from southern latitudes to Norway in spring and early summer also favors formation and transport of biogenic secondary organic aerosol (BSOA). Further, such warm air masses can also initiate emission of PBAP locally in Norway. Additional tracer analysis is needed to assess if this was the case also in April 2019.

Secondary inorganic aerosol (SIA) were not signature species of the two events but still made a 20 – 22% contribution to PM₁₀. Contribution from sea salt aerosol was negligible (<2.5%).

To sum up, the chemical composition of the aerosol particles points to mineral dust (24 – 27%), carbonaceous aerosol from agricultural fires (17 – 34%), carbonaceous aerosol from other sources than agricultural fires (29 – 34%) and SIA (20 – 22%) as the major sources of the elevated PM levels observed at Birkenes in April 2019.

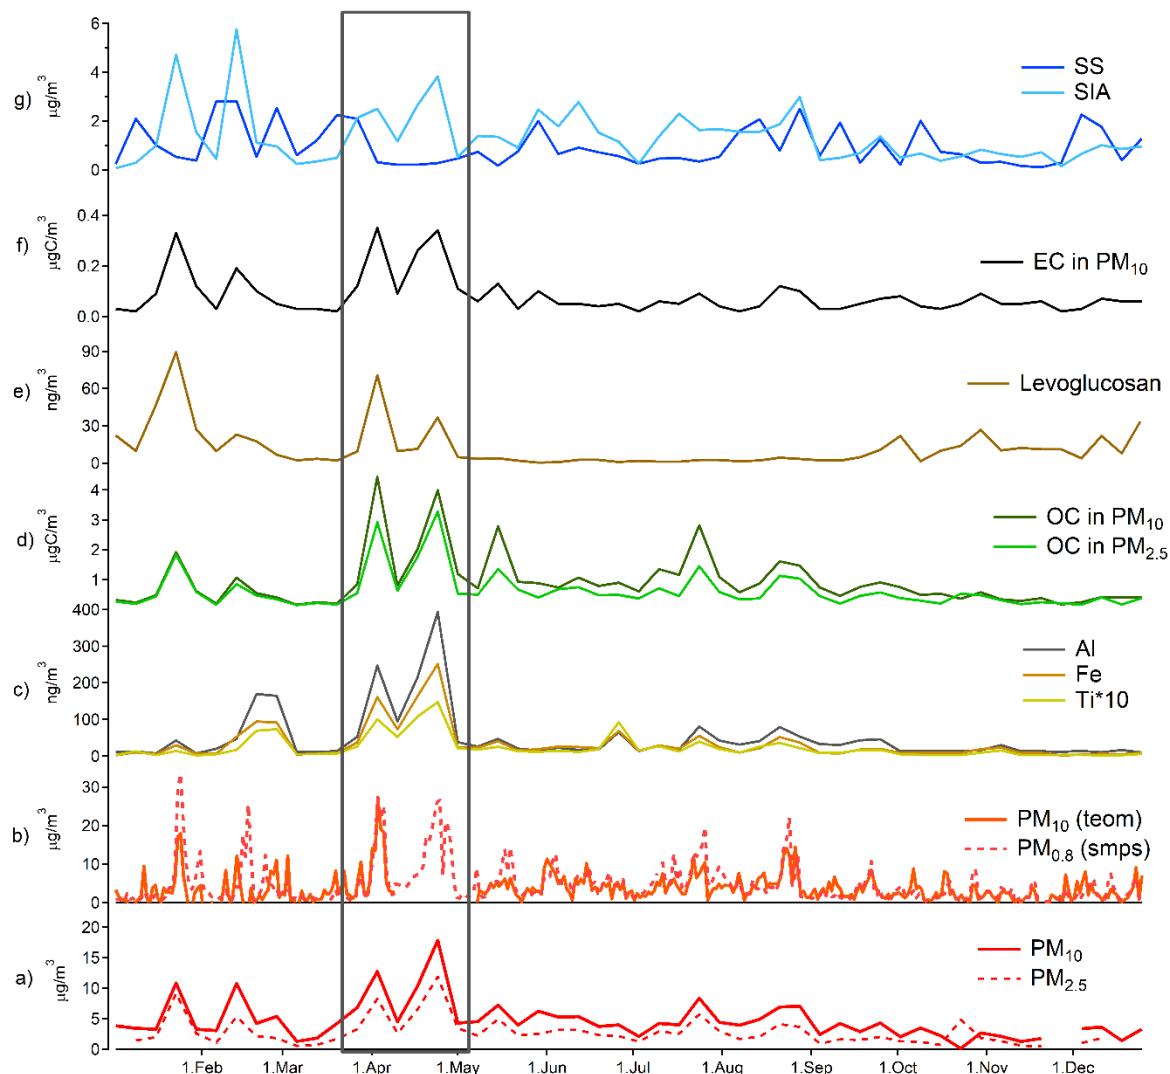

Figure 7.6: Mass concentration (weekly) of PM_{10} and $\text{PM}_{2.5}$, (panel a); Mass concentration (24-hour) of PM_{10} and $\text{PM}_{0.8}$ (panel b); Aluminum (Al), iron (Fe) and titan (Ti) in PM_{10} (weekly) (panel c); Organic carbon (OC) in PM_{10} and $\text{PM}_{2.5}$ (weekly) (panel d); Levoglucosan in PM_{10} (weekly) (panel e); EC in PM_{10} (weekly)(panel f); Secondary inorganic aerosol (SIA = Sum of SO_4^{2-} , NO_3^- and NH_4^+) and sea salt aerosol (SS = Sum of Na^+ , Cl^- and Mg^{2+}) (24-hour) (open filter face) (panel g). All measurements are from the Birkenes Observatory.

Annex 3

Sampling and chemical analysis (incl. background information on PM and EC/OC and levoglucosan)

Main components in precipitation

For precipitation sampling, a NILU Precipitation Collector (funnel + bucket type) is used (P.no. 9713, RS1). The bucket has a size of 2.5 litre, and the diameter of the collecting surface is 200 mm. The collector is placed 2 meters above ground. In winter, during snow conditions, the bulk + funnel collector is exchanged with a so-called Particulate Fallout Collector (P.no. 9711, SF1), see figure on the right of the two bulk collector types. The material used for the collectors is high density polyethylene.

The precipitation sampler is emptied and cleaned with distilled water between each sampling period (daily or weekly), also in periods when there has been no precipitation. The precipitation amount is measured by volume at the site, and an aliquot of the sample is sent to NILU for chemical analysis.

pH is measured with potentiometric method and conductivity with a conductivity meter. Anions and cations are measured with an ion chromatograph. The detection limit for the different ions are given in the table below:

Parameter	Detection limit (unit)
SO_4^{2-}	0.01 (mg S/l)
NO_3^-	0.01 (mg N/l)
NH_4^+	0.01 (mg N/l)
Na^+	0.01 (mg Na/l)
Cl^-	0.01 (mg Cl/l)
K^+	0.01 (mg K/l)
Ca^{2+}	0.01 (mg Ca/l)
Mg^{2+}	0.01 (mg Mg/l)

Main components in air

The main ions in air is sampled with a three stage filterpack using the NILU filter holder system designed for sampling of particles and gaseous compounds, see figure below. The first filter in the air stream is an aerosol filter (Zeflour 2 μm) for collecting the airborne particles containing SO_4^{2-} , NH_4^+ , NO_3^- , Ca^{2+} , K^+ , Cl^- , Na^+ . This is followed by an alkaline (KOH) impregnated filter (Whatman 40), which will collect HNO_3 , SO_2 , HNO_2 , HCl , and other volatile acidic substances. Nitric acid and sulfur dioxide will react with potassium hydroxide on this impregnated filter to give potassium nitrate and potassium sulphite. Oxidizing species in air e.g. ozone are believed to convert most of the sulphite to sulfate during the sampling. The third filter (Whatman 40) is acid-impregnated (oxalic acid) for absorbing alkaline air component such as NH_3 . The filter pack method is biased in separating gaseous nitrogen compounds from aerosols and therefore the sum is reported. In other words, the concentration of nitrates in air equals the sum of the nitrate found on the aerosol filter and nitrate found on the alkaline impregnated filter. The same for ammonium, where the sum of ammonium concentration equals the sum of ammonium collected on the aerosol front filter and ammonia collected on the acid impregnated filter.

The filterpack samplers does not have a pre-impactor, but the air intake has a cylindrical vertical plastic section covering the filter holder – about 15 cm wide and 25 cm high. This air intake reduces the sampling efficiency for large particles such as soil dust particles, large sea spray droplets, large pollen,

and fog droplet, thus the size cut off is approximately PM₁₀ except for strong sea salt episodes when larger particles are collected.

After exposure, the filter holders are sent to NILU for chemical analysis. The filters are put into a test tubes with additions of extraction solution. Hydrogen peroxide solution is used for the alkaline filter in order to oxidize any remaining sulphite to sulfate. An HNO₃ is added to the acid impregnated filter. The aerosol Teflon® filters are given an ultrasonic treatment before analysis in order to obtain a complete extraction. The ions are analysed using an ion chromatograph, and the detection limits are given below:

Parameter	Detection (unit)	limit
SO ₂	0.01	(µg S/m ³)
SO ₄ ²⁻	0.01	(µg S/m ³)
Sum (NO ₃ ⁻ +HNO ₃)	0.01	(µg N/m ³)
Sum (NH ₄ ⁺ +NH ₃)	0.05-0.1	(µg N/m ³)
Na ⁺	0.02	(µg Na/m ³)
Cl ⁻	0.02	(µg Cl/m ³)
K ⁺	0.02	(µg K/m ³)
Ca ²⁺	0.02	(µg Ca/m ³)
Mg ²⁺	0.02	(µg Mg/m ³)

Nitrogen dioxide

NO₂ is determined with the manual NaI glass sinter method. Ambient air with a flow rate of about 0.5 l/min is drawn through an air intake (inverted funnel) and a glass filter impregnated with sodium iodide (NaI) and sodium hydroxide (NaOH). Nitrogen dioxide is absorbed in the filter, and the iodide reduces NO₂ to nitrite. The nitrite formed on the glass filter is extracted with deionized water. After extraction the nitrite concentration can be determined spectrophotometrically at 540 nm after a reaction with sulphanilamide and N-(1-naphthyl)-ethylenediamine (NEDA). The detection limit for this method is 0.03 µg N/m³.

Ozone

Ozone (O₃) is determined with the UV-absorption method (UV light at 254 nm) using a monitor with continuous measurements. The results are given in hourly resolution.

Particles (Mass, EC/OC, and levoglucosan)

Background

Size is the most fundamental parameter describing an aerosol, being decisive for transport and removal, and essential for understanding the effects of the ambient aerosol. Aerosols are most commonly defined by their equivalent aerodynamic diameter, defined as, that of a spherical particle of unit density (1 g cm^{-3}), having a settling velocity equal to that of the particle in question. The size distribution of the tropospheric aerosol is commonly divided into three major modes (Whitby, 1978); the nuclei mode, the accumulation mode and the coarse mode, all having different formation processes, leading to different characteristics of the aerosol. Tropospheric aerosols are either emitted directly (primary) or formed in the troposphere by oxidation of precursor gases (secondary) (Seinfeld and Pandis, 1998). The sources of tropospheric aerosols are both natural (e.g. windborne dust, sea spray, volcanic activity, biomass burning) and anthropogenic (fuel combustion, industrial processes, non-industrial fugitive sources and transportation sources), and hence its chemical composition is highly diverse, including amongst others: sulfate (SO_4^{2-}), nitrate (NO_3^-), ammonium (NH_4^+), organic carbon (OC), which is a bulk fraction of numerous organic molecules, light absorbing/refractory carbon (BC/EC), aluminum and silicon (major constituents of mineral dust), inorganic cations (e.g., K^+ , Na^+ , Ca^{2+} , Mg^{2+}) and anions (e.g., Cl^-).

The adverse health effects of the ambient aerosol is well recognized (e.g., Dockery et al., 1993; Schwarz et al., 1996), causing various types of cardiopulmonary diseases, e.g., chronic obstructive pulmonary disease, ischemic heart disease, lung cancer and pneumonia. Although the statistical evidence between ambient air particulate mass (e.g., PM_{10} and $\text{PM}_{2.5}$) and adverse health effects are well documented, there is considerable doubt concerning the causal relationship. Thus, other relevant parameters such as the particle number size distribution, the surface and the chemical composition of the aerosol must be considered when addressing this issue. There is strong evidence that fine particles are more hazardous than coarse ones (Schwartz et al., 1996, Schwartz and Neas, 2000), although coarse particles are associated with adverse health effects as well (Castillejos et al., 2000; Ostro et al., 2000). An increasing number of experimental studies have been devoted to the number of ultrafine particles ($d_p < 100 \text{ nm}$), which potentially play a role in the cardiovascular effects commonly associated with exposure to particulate matter (Donaldson et al., 2001). Concerning the chemical composition, WHO has given the general advice that primary combustion derived particles are particularly important as they *"are often rich in transition metals and organic compounds, and also have a relatively high surface area"*. However, more knowledge is needed concerning the ambient aerosol chemical composition and its contribution to the adverse effects seen on human health.

The tropospheric aerosol has an influence on the radiation budget both directly, by scattering and absorption of sunlight and terrestrial radiation, and indirectly, by influencing cloud reflectivity and lifetime. Both effects lead to a mostly cooling effect for the Earth's surface. The particle size distribution is essential for quantifying the magnitude of both direct and indirect aerosol climate effect, whereas particle chemical composition influences aerosol absorption and the lower size limit of particles acting as cloud condensation nuclei.

The tropospheric aerosol also plays an important role when it comes to acidification and eutrophication of water bodies. This is attributed to the content of secondary inorganic species such as SO_4^{2-} , NO_3^- and NH_4^+ , which typically are associated with accumulation mode particles, enabling long-range transport and deposition in regions far from where the precursors were emitted.

Elemental (EC) and organic (OC) carbon are abundant fractions of the ambient aerosol particle, thus contributing to the aerosol particle influence on the radiation budget both directly, by scattering and

absorption of sunlight, and indirectly, by cloud formation. Likewise does the carbonaceous fraction contribute to the adverse health effects observed; i.e., respiratory and cardiovascular diseases. EC enters the atmosphere exclusively as a primary (i.e., direct particulate) emission, whereas OC includes both primary aerosol particles and secondary aerosol particles, of which the latter is formed from gaseous precursors oxidized in the atmosphere. The carbonaceous fraction can be of both anthropogenic and natural origin; e.g., EC and OC from incomplete combustion of fossil fuel (e.g. vehicular tailpipe emissions) and biomass (residential wood burning and wild fires), OC from oxidation of gaseous emissions from coniferous and deciduous trees, and OC associated with primary biological aerosol particles (PBAP). EC and OC are typically associated with the fine aerosol particle, although OC can appear in the coarse fraction as well, e.g. the PBAPs or due to condensation of OC on coarse aerosol particles. Despite the importance of the carbonaceous aerosol, detailed apportionment and quantification of its sources is still difficult due to the large number of sources, the complexity of atmospheric formation and the vast number of organic compounds associated with the aerosol.

EC and OC are simply operational definitions, and do not provide information about the source *pr. se*, thus additional measurements to EC and OC are required to provide information about the carbonaceous aerosol sources and their relative share. Source apportionment studies (Yttri et al., 2011a, b), using a combination of ^{14}C and organic tracers, show that natural sources dominates OC in PM_{10} at Norwegian rural background sites in summer, of which OC associated with the biogenic secondary organic aerosol (BSOA) is the major source followed by OC associated with PBAP. In winter, anthropogenic sources dominates OC in PM_{10} , i.e., emissions from fossil fuel combustion and residential wood burning. The picture is rather similar for OC in PM_1 , except that OC associated with PBAP is of much less importance in summer than seen for PM_{10} . Combustion of fossil fuel appears to be the major source of EC regardless of season and size fraction, but EC from residential wood burning increases substantially in winter.

Levoglucosan is a thermal degradation product of cellulose with a low vapor pressure and a high emission factor from combustion of biomass (Locke, 1988; Simoneit et al., 1999; Oja and Suuberg, 1999), and thus well suited to trace biomass-burning aerosol in the ambient atmosphere. Aqueous-phase reaction with OH radical in deliquescent particles appears to be the most efficient pathway causing depletion of levoglucosan in the atmosphere. The $\frac{1}{2}$ values (the time until half of the levoglucosan has been degraded) for levoglucosan in the atmosphere is debated and likely to vary with photochemical activity and OH concentrations, being a function of temperature and season (Hennigan et al., 2010; Yttri et al., 2014).

Levoglucosan is considered the most robust and reliable tracer of biomass burning, and is commonly used to trace biomass burning aerosol, not only qualitatively, but also quantitatively by combining ambient concentrations with emission ratios, or as input along with other species to e.g. positive matrix factorization (PMF). For studies using levoglucosan as biomass burning tracer in Norway, see Yttri et al., 2005, 2007a, b, 2009, 2011a, b, 2014, 2019, in prep. Although levoglucosan appears to be best suited to trace biomass burning emissions in winter and on a local to regional scale, conservative estimates of the biomass burning aerosol concentration can still be provided for the remote environment.

Emission ratios used to convert observed ambient concentrations of levoglucosan to OC and EC from biomass burning, are associated with great uncertainty. In the present report, we use an OC/levoglucosan ratio of 12.7 and an EC/levoglucosan ratio of 1.96. These ratios are based on positive matrix factorization (PMF) analysis results for PM and PM species observed at Birkenes (Yttri et al., in prep.), which are consistent with results presented in the scientific literature e.g. by Zotter et al. (2017). A factor of 2 was used to convert biomass burning OC to OM, and a factor of 1.1 for biomass burning EC.

Sampling and chemical analysis

PM₁₀ and PM_{2.5} are obtained using Kleinfiltergerät samplers (one sampler pr. size fraction), collecting filter samples on a weekly basis. The ambient aerosol particles are collected on prefired (850 °C for 3 hrs) quartz fibre filters (Whatman QM-A, 47 mm). The quartz fibre filters are conditioned (20 °C; 50% RH; 48 hrs) prior to and after being exposed. The mass concentration of the quartz fibre filters are determined gravimetrically. The uncertainty of the PM mass concentrations obtained for PM₁₀ and PM_{2.5} is estimated to be around 0.1 – 0.15 µg/m³ for a sampling volume of 386 m³.

Number concentration measurements at Birkenes dates back to 2010. The number concentration of ultrafine particles ($D_p < 0.1 \mu\text{m}$), accumulation mode particles ($0.1 \mu\text{m} < D_p < 1.0 \mu\text{m}$) and coarse mode particles ($D_p = 0.01 - 10 \mu\text{m}$) are obtained by combined measurements of a Differential Mobility Particle Spectrometer (DMPS) and an Optical Particle Spectrometer (OPS). The DMPS measures the particle number size distribution ranging from 0.01 – 0.8 µm particle diameter, whereas the OPS covers the range from 0.25 µm to 30 µm. The DMPS and the OPS provide method specific measures of the particle diameter, i.e. the electrical mobility particle diameter and the optical particle diameter, respectively. Thus, when merging these two measures into one particle number size distribution (PNSD) time series, the PNSD must agree within 25% in particle diameter in their overlapping size range.

In May 2017 a continuous, direct aerosol mass instrument was installed at Birkenes, a so called tapered element oscillating microbalance (TEOM) instrument with a size cut off to measure PM₁₀ mass. The TEOM Monitor draws (then heats) ambient air through a filter at constant flow rate, continuously weighing the filter and calculating near real-time mass concentrations of particulate matter. The mass is corrected with a factor 1.1 based on an intercomparison campaign which the TEOM with gravimetric measurements, which is the reference method.

Thermal-Optical Analysis of EC, OC and TC in PM₁₀ and PM_{2.5} are performed on the same filter samples as the mass concentration of PM₁₀ and PM_{2.5} are obtained from for the sites Birkenes, Hurdal and Kårvatn. At Zeppelin, ambient aerosol filter samples for subsequent analysis of OC, EC and TC were obtained using a Digitel high-volume sampler with a PM₁₀ inlet, collecting filter samples on a weekly basis. These quartz fibre filters (PALLFLEX Tissuequartz 2500QAT-UP; 150 mm in diameter) were prefired (850 °C for 3 hrs) but not conditioned, and were arranged according to the quartz fiber filter behind quartz fiber filter (QBQ) set up, which allows for an estimate of the positive sampling artefact of OC. The T-O analysis are performed according to the EUSAAR-2 protocol (Cavalli *et al.*, 2010). The analytical detection limit of the TOA instruments is 0.2 µg C/cm², corresponding to methodological detection limit of 0.007 µg C m⁻³ for a sampling volume of 386 m³ and an exposed filter area of 13.4 cm² for the sites Birkenes, Hurdal and Kårvatn, and a detection limit of 0.005 µg C m⁻³ for a sampling volume of 6720 m³ and an exposed filter area of 154 cm² for Zeppelin.

Concentrations of the biomass burning tracer levoglucosan (mannosan and galactosan) is determined in the same PM₁₀ filter samples as the mass concentration, EC, OC and TC, using ultra-performance liquid chromatography (UPLC) in combination with high-resolution time-of-flight mass spectrometry (HR-TOF MS) operated in the negative electrospray ionization (ESI-) mode, and according to a modified version of the analytical method described by Dye and Yttri (2005). The methodological detection limit is approximately 20 – 90 pg m⁻³ for a sampling volume of 386 m³ and an exposed filter area of 13.4 cm².

NILU – Norwegian Institute for Air Research

NILU – Norwegian Institute for Air Research is an independent, nonprofit institution established in 1969. Through its research NILU increases the understanding of climate change, of the composition of the atmosphere, of air quality and of hazardous substances. Based on its research, NILU markets integrated services and products within analyzing, monitoring and consulting. NILU is concerned with increasing public awareness about climate change and environmental pollution.

NILU's values: *Integrity - Competence - Benefit to society*

NILU's vision: *Research for a clean atmosphere*
